Fig. 24

Fig. 5

Fig. 23. Roentgenogram taken 5 years after protrusion of the fifth lumbar disc was removed. The preoperative roentgenogram was normal. This film shows narrowing of the fifth disc and also of the fourth disc.

Fig. 24. Roentgenogram taken 4 years after protrusion of the lumbosacral disc was removed. The preoperative

roentgenogram was normal. This film shows narrowing of the fifth disc and also of the fourth disc.

Fig. 25. Roentgenogram taken 3 years after a protrusion of the fourth disc was removed. The preoperative roentgenogram was normal. This roentgenogram shows narrowing of the fourth disc and also of the fifth disc.

Follow up after from 1 to 5 years showed that 11 patients were cured, 5 had a slight recurrence, 1 had marked pain, and 4 could not be traced.

Two of the cured patients complained of weakness of the back and 1, although without sciatic pain, had persistent pain in front of the thigh.

The results from 12 to 18 months after operation in the military cases showed that no patients were cured, 5 were benefited, and 12 were not benefited.

After from 1 to 5 years, 6 of the military patients were in Category E and 11 were in Category C. (British Army Medical Classification.)

Thickened ligamentum flavum—(14 cases) The immediate results showed that 10 patients were cured, 3 were benefited, and 1 patient was not benefited. Follow up after from 1 to 5 years later showed that 5 patients remained symptomless, 6 had some sciatic pain, and 3 could not be traced.

No pathology discovered in disc or ligamentum flavum (15 cases)

Of these patients, 9 were subjected to spinal arthrectomy either combined with laminectomy or followed by laminectomy and the results have already been considered.

The remaining 6 cases include the 2 in which an exudate (considered to be the result of lipiodol injection) was found around the nerve roots.

The immediate results showed that 4 patients were cured, 1 was benefited, 1 not benefited.

Follow up after from 1 to 5 years showed that 3 patients remained symptomless, 1 patient had some sciatic pain, and 2 patients could not be traced.

Spondylolisthesis (1 case) Laminectomy was performed. There was no disc protrusion. A spinal fusion was done. The patient obtained partial relief.

TABLE IV — THE OPERATIONS AND THE TOTAL RESULTS

Result	Disc	Ligt. Flavum	No Pathology	Spondy. Isthmect.	Arthrectomy	Total
Cured	11	5	3	0	25	44
Still having pain	24	6	1	1	22	54
Not traced	8	3	2	0	3	16
Total	40	14	6	1	50	116

Fig. 26

Fig. 27

Fig. 26. Roentgenogram taken 3 years after a "concealed disc" (lumbosacral) had been exposed. At the operation no disc material was removed. The preoperative roentgenogram was normal. This roentgenogram shows narrowing of the fifth disc and also of the fourth disc.

Fig. 27. Roentgenogram taken 3 years after a protrusion of the fifth disc was removed. The preoperative roentgenogram was normal. This roentgenogram shows narrowing of the lumbar sacral disc and also of the third and fourth discs.

The consolidated operative results are shown in Table IV. Following the disc operations (including the military cases) 11 of 40 patients were cured (27%) or 11 of 35 cases that were traced were cured (31%).

Following arthroectomy 25 of 55 patients were cured (45%) or 25 of 47 cases that were traced were cured (53%).

This survey is incomplete because of the war-time difficulty of follow-up but it is sufficiently clear that the results of operation for disc protrusion are not uniformly good. It must however be emphasized that the results are satisfactory in the sense that when pain persists or recurs it is never as severe or disabling as the preoperative pain.

All the civilian patients were satisfied with the operation.

The possible causes of persistence or recurrence of pain after operation are obvious. The disc necessarily remains defective after operation whether it is a concealed bulging or degenerated disc from which no material is removed or a disc with a definite sequestrum. In the last case excision of the sequestrum removes the immediate cause of the pain but it does not restore a normal

anatomy. The spinal blemish is permanent and may be a cause of reflex pain. It also weakens the back, and patients do in fact, frequently complain of continued backache and a feeling of weakness in the back after operation. Further a recurrent protrusion may occur. Love and Walsh report recurrence in 2 per cent of their cases.

In our series there was 1 case of proved recurrence in which 2 years after removal of a prolapsed nucleus had completely cured the sciatica, severe recurrence of pain occurred on the same side. A second operation was performed and a large protrusion at the same level was removed. Much material came away as though almost the whole of the disc remaining after the first operation had degenerated (Fig. 21).

This case also illustrates yet another complication—narrowing of the disc after a protrusion has been removed. The original roentgenogram of this patient showed nothing abnormal, but at the time of the second operation the lumbosacral disc was a little narrowed. Three months after the second operation the lumbosacral disc was attenuated, and there was subluxation of the lateral joints at this level and a little backward displacement of the fifth lumbar vertebral body. Subsequent

roentgenograms showed progressive narrowing of the disc (Fig. 22). This patient continues to have pain, now less severe than before the recurrent protrusion was removed, but it is likely to become progressively worse.

Postoperative narrowing of the disc space is, of course, a significant finding; the mechanical result of acquired narrowing being posterior displacement of the upper vertebral body subluxation of the lateral joints between the two bodies, and constriction of the intervertebral foramen.

At the present time we have been able to obtain late postoperative roentgenograms of only 17 of our disc cases (including the case illustrated in Fig. 22). The preoperative roentgenograms in each of the 17 cases were normal. In 10 of these cases, however, the late postoperative roentgenograms show degenerative changes, as follows:

In 4, the disc operated upon has become narrow.

In 5 there is narrowing of the disc operated upon, and also narrowing of an adjacent disc (Figs. 23-26).

In 1 case there is narrowing of the disc operated upon, and of two other discs, in addition (Fig. 27).

It is clear therefore, that progressive post operative degeneration of one or more discs is by no means uncommon. This fact must be considered in planning the treatment in these cases. The object of the operation should be, not only to relieve the pressure on a nerve root, if indeed any root is being pressed upon, but also to avoid ill effects from the subsequent degeneration which may be expected.

SELECTION OF CASES FOR OPERATION

There is no doubt that cases with abnormal neurological signs indicating pressure on a nerve root and interference with conduction in the root give better immediate results than those in which the pain is of a referred type, without any interference with conduction. Those with abnormal neurological signs recover more quickly and more completely. The immediate relief from severe pain is striking. When there is no loss of conduction the immediate results are often disappointing. The pain is at first only partially relieved and recovery which progresses slowly over a period of months, may in the end be incomplete.

These observations raise the question of the type of operation to be performed.

1 When a protrusion is to be removed, a laminectomy with ample bone removal and wide exposure is advisable.

2 If there is no protrusion, but the disc is degenerate, it was for some time our custom to complete the operation as an arthrectomy and to

remove the lateral joint. This operation "decompresses" the nerve root and, as a rule, gives satisfactory results. In some cases of this sort, however spinal fusion has been done, i.e., when the presence of degeneration without protrusion has been verified, an Albee graft is applied, the laminae and lateral joints being left intact. This procedure seems rational, the fusion being intended to protect the degenerated disc from further strain or injury. Further observation will determine its value.

3 For cases with arthritic changes in the lateral joints, confirmed by roentgenography arthrectomy is the operation of choice. These changes are usually found in patients in the fifth or sixth decades.

When the laminae have been exposed in the approach to the joints, it is advisable to explore the interlaminar spaces to make certain that the discs are normal before the joints are excised.

SUMMARY

1 A modern tendency to overemphasize the importance of the protruded intervertebral disc as a cause of sciatica is noted.

2 The nature of sciatic pain is analyzed with particular attention to the importance of referred pain.

3. The clinical characteristics, diagnosis, and differential diagnosis of sciatica are discussed.

4. The article is based upon a study of 298 cases of sciatica.

I wish to record my gratitude to Mr. Blundell Bankart and to Mr. Philip Wiles for so kindly placing their case records at my disposal, and to Miss Muriel Crouch for her expert help in the preparation of this article, and in the treatment of many of the cases recorded in it.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

EYE

Lee Otis S., Jr.: Corneoepidural Suture in Operations for Cataract, with Special Reference to the Incidence of Postoperative Hypphema. *Arch Ophth., Chic.*, 1947 37 59

Recent investigations have shown that the source of postoperative hemorrhage into the anterior chamber is from the new blood vessels that are growing into the incision. Any separation of the lips of the wound tears these vessels and results in bleeding under the conjunctiva or more frequently into the anterior chamber.

The purpose of this article is to compare the occurrence of postoperative anterior chamber hemorrhage in those patients who have had three or more interrupted limbic-epidural sutures for the closure of the incision with such occurrence in patients who have had a modified Liépard suture with a additional limbic-epidural sutures. In placing this modified Liépard suture the globe is fixed with a Burch pick which is placed opposite the point at which the needle is to penetrate the corneal tissue. A bite is taken in the limbus at twelve o'clock, parallel to the limbus and from 1.5 to 2 mm. wide. The thread is pulled through until it is stopped by a previously prepared double knot about 3 cm. from the end. The needle is reversed and with fixation, is transferred to the opposite side. A bite is taken from 1.5 to 2 mm. above the first one, the needle passing through the conjunctiva and scleral tissue and out again. The scleral bite is equal in width, and lies exactly opposite to the limbic suture.

In the first 150 cases from 3 to 5 interrupted limbic-epidural sutures were used in one half of this series a complete iridectomy was done whereas in the other half only a small peripheral iridectomy was done. No significant difference in the number of hemorrhages into the anterior chamber was found between these two groups. In the next series of 50 cases a modified Liépard stitch was used in addition to the interrupted corneoepidural sutures. In this group all cataracts were extracted through an intact sphincter pupillae with a small peripheral iridectomy performed in each case. A comparison showed an incidence of postoperative hypphema in 15.3 per cent of the first series and in 6.6 per cent of the second series in which the modified Liépard suture was used. In the second series the bleeding was less severe.

The author postulates that the poor results with the interrupted limbic-epidural sutures may have been due to the fact that many were limbic-conjunctival rather than epidural and therefore unable to hold the wound in as close apposition. The

modified Liépard suture is preferred since it is easy to place, requires no conjunctival flap may be quickly closed and may be used to open the wound for the insertion of instruments. Care should be taken that the horizontal bites are placed opposite each other and that the sutures are not tied too tightly.

ROBERT H. JOHNSON, M.D.

Owens, William Councilman; and Hughes, William F., Jr.: Intracocular Hemorrhage in Cataract Extraction. *Arch Ophth., Chic.*, 1947 37 56

The authors reviewed 3,086 extractions of uncomplicated senile cataract to determine what factors in the patient's physical status or in the operative technique produced intracocular hemorrhage, how these factors could be controlled and what effect each type of hemorrhage had on the post-operative course and visual result. Three types of intracocular hemorrhage were evaluated in this study. Postoperative hemorrhage into the anterior chamber occurred in 9.3 per cent of the cases 3.6 per cent of these were designated as severe because the hemorrhages either filled the anterior chamber completely or were recurrent. The most frequent time of onset was between the second and the sixth days. The age, blood pressure, and prothrombin levels had no relationship to the post-operative hemorrhage.

The diabetics as a group showed only a slight increase in the tendency toward postoperative hypphema; however diabetics of long standing or who required large amounts of insulin showed a sharp increase in the incidence of severe hemorrhage. The blood sugar level or presence of central retinitis made no difference in the incidence of postoperative hemorrhage. Syphilis and the presence or absence of foci of infection had no bearing.

The type of extraction had an effect on the number of hemorrhages but both the use of a corneoepidural suture and a shallow section reduced the incidence considerably. There was a very slight increase in the incidence of postoperative hemorrhage into the anterior chamber following full iridectomies, and a progressive increase in hemorrhages with the loss of increasing amounts of vitreous. No relationship was found between postoperative hemorrhage and the visible gaping of the wound, delayed reformation of the anterior chamber, prolapse of the iris, or iridocyclitis. The authors believed that the bleeding resulted from the rupture of the small capillaries that had grown into the healing incision.

The major cause of the significantly poorer visual results in cases of postoperative hemorrhage into the anterior chamber was found to be due to seepage of blood into the vitreous with its resultant opacities.

Postoperative hemorrhage did not predispose to late secondary glaucoma or phthisis bulbi. Blood remained more frequently in the anterior chamber at the end of the operation because of unusually severe bleeding in older patients and in patients in whom the sections had been placed more deeply and had no effect on the visual results.

To this series there were 3 explosive hemorrhages which the authors did not believe were related to the blood pressure.

ROGER H. JOHNSON, M.D.

Yasuna, Elton R.: Danger of Penicillin Therapy in Active Uveitis. *Arch Ophthalmol* 1947 37 598

Since even following massive doses only negligible amounts of penicillin reach the aqueous vitreous and lens by intravenous, intramuscular and oral routes, other methods of administration have been employed in ophthalmology. Application directly to the cornea and conjunctiva gives excellent concentrations on the anterior surface of the globe. The use of iontophoresis, wetting agents, and cotton packs saturated with penicillin and placed in the lower fornix has proved a satisfactory and convenient method of obtaining higher levels in the cornea, aqueous, iris and ciliary body. Penicillin has been found to be excellent in the treatment of ophthalmia neonatorum and to be a therapeutic aid in both acute and chronic trachoma; however reports by various authors on the value of penicillin in the treatment of infectious conditions of the inner eye have not been in agreement.

The author cites a case of acute iridocyclitis, one a recurrent type and the other following traumatic surgery which were treated by the usual methods in addition to small intramuscular doses of penicillin. Both cases became progressively worse but on cessation of the penicillin therapy showed rapid improvement. Recent investigations have tended to show that a uveitis may be caused by a hypersensitivity of the eye to the bacterial products emanating from the primary focus of infection rather than to bacteria lodging in the uvea. Penicillin is generally agreed to be not only bacteriostatic but also bacteriocidal. The author suggests that the use of penicillin kills bacteria in the foci and releases more bacterial end products into the blood stream. This increases the amount of bacterial toxins in the blood stream and thereby increases the already active uveitis. By stopping the penicillin and thereby stopping the breakdown of the bacteria, the uveitis could improve.

Since most observers believe that penicillin is not of value in uveitis, the author thinks that it would be more advisable not to employ the drug especially when it may actually be dangerous.

ROGER H. JOHNSON, M.D.

Zondek, H. and Wolfsohn G.: Glaucoma and Pituitary Function. *Am J Ophthalmol* 1947 30 596

The authors discuss the relationship between primary glaucoma and the pituitary-diencephalic system. They point out that endocrine factors such as

the thyroid, pituitary gonads, and the corticoadrenal system have been considered as possibly responsible for primary glaucoma. A similar relationship between a number of other ocular diseases (retinitis pigmentosa, the Lawrence-Moore-Biedl syndrome, pituitary-diencephalic exophthalmos, etc.) and the pituitary body (the diencephalic pituitary system) has been established.

In a series of 22 cases of primary glaucoma, tests were made of the carbohydrate and water metabolism, basal metabolism, blood cholesterol and of the osseous structure of the skull. Of these 16 cases presented evidence which indicated disturbances in the pituitary-diencephalic system: obesity, menstrual disturbances, disordered carbohydrate metabolism, water retention, abnormal basal metabolic rates, elevated blood cholesterol, decalcification or atrophy of the sella turcica (occasionally calcification) and congestion of the meningeal vessels. Six of the 16 patients presented pituitary tumors, and 2 of these presented characteristics of acromegaly.

Only 6 of the total number of 22 cases presented no evidence of pituitary-diencephalic disturbances.

The authors suggest the term pituitary diencephalic glaucoma, to correspond with the accepted term pituitary-diencephalic exophthalmos, to designate those cases of primary glaucoma which present pituitary-diencephalic symptoms.

JOSHUA ZUCKERMAN, M.D.

Reese, A. B.: Pigmented Tumors. *Am J Ophthalmol* 1947 39 537

The author discusses pigmented tumors. Melanoblasts produce pigment called melanin. Because little is known about these cells and their product, great differences of opinion exist regarding them.

The term melanin is applied to any black, brown or tan pigment and any heterogeneous group of pigments which possess the common characteristic of absorbing visible light uniformly.

There are various types of melanoblasts from which various types of tumors arise.

Ophthalmologists encounter nevi of the skin, of the eyelids and more commonly of the conjunctiva particularly at the limbus and coruncle.

Nevi are congenital but are not visible at birth. They grow during the first decade of life and become pigmented between the ages of 4 and 14 years especially at puberty at which time they are usually noticed first. They regress in later life and occasionally disappear spontaneously and completely. A nevus can develop into a malignant tumor but this occurs very rarely.

It is pointed out that pigmented tumors seem to differ genetically, histologically and clinically but all have one factor in common—pigment. The pigment is so conspicuous that it dominates the histologic and clinical picture. The author believes that instead of diagnosing all tumors which harbor pigment as melanomas, they should be designated by terms which connote their separate entities. He suggests the following terminology: (1) benign and

SURGERY GYNECOLOGY AND OBSTETRICS

VOLUME 85

JULY, 1947

NUMBER 1

RADICAL SINGLE STAGE EXTIRPATION FOR CANCER OF THE LARGE BOWEL, WITH RETAINED FUNCTIONAL ANUS

W WAYNE BARCOCK, M.D. F.A.C.S. Philadelphia, Pennsylvania

FOR years the Miles operation for cancer of the rectum and rectosigmoid has been the most popular procedure of North American surgeons. The operation has been found to be radical, the technique is not difficult to master and in skilled hands the mortality has been relatively low. The operation, however, has not been popular with the patient, for he objects to the abdominal colostomy, the postoperative impotence, the not infrequent persistent urinary dysfunction and the occasional abdominal or perineal hernia. The operation also removes the means of making an early diagnosis of a pelvic recurrence by palpation through the bowel. These objections are largely due to the removal of the anus and part of the pelvic floor based

upon Miles's belief that rectal cancers spread downward, upward, and laterally. The pathological studies of Westhuys and others (4-9) have shown that it is rare for rectal cancer to invade tissues more than 3 centimeters below the growth, which also is corroborated by our own clinical experience. As the anus with its different lymphatic spread, is primarily involved in hardly 3 per cent of cancers of the large bowel it is evident that for most patients with cancer of the rectum sacrifice of the anus and pelvic floor is unnecessary. However the marked tendency to an upward and lateral lymphatic extension of rectal cancer can properly be met only by exposure and liberation through the anterior abdominal wall. Beginning in 1904 I tried various perineal and sacral methods of resection for cancer of

in a towel and laid over the pubis. The sigmoid is held against the pubis by a towel, the pelvis is inspected and cleared of clots, and the first deep suture of No. 32 stainless steel wire has been inserted into the levators but not tied.

Fig. 9. The open pelvic floor is being closed in the mid line by three rows of buried interrupted sutures of No. 32 wire.

Fig. 10. The skin has been closed with interrupted sutures of No. 35 wire. The divided sphincters are not united.

Fig. 11. A finger tests the wound closure to make sure that the sigmoid will not be strangulated by secondary swelling.

Fig. 12. Perineal gauze dressings moistened with compound tincture of benzoin have been applied, the sigmoid has been divided 6 centimeters from the skin, and a No. 28 rectal tube has been tied in.

Fig. 1. The midline perineal incisions used.

Fig. 2. The incision divides the sphincters posteriorly and passes through the pelvic floor to the right side of the coccyx, which is not removed.

Fig. 3. The rectum is divided by scissors just above the sphincters as the upper rectal edge is grasped by a series of forceps.

Fig. 4. Four hemostatic forceps have now been attached to the upper edge of the partly divided rectum for light traction. The isolated gauze within the rectum is shown.

Fig. 5. Rectosigmoid free from all lower attachments.

Fig. 6. The rectosigmoid is withdrawn from the pelvis with the attached gauze tape, which indicates the lowest level of viable sigmoid.

the rectum, with or without retention of the anus but, like others, found these operations sufficiently radical and associated with too high a percentage of postoperative complications. Turning to the more radical abdominoperineal operations, by 1939 I began to do the resection without colostomy or mutilation of the pelvic floor. In the development of the operation it was found that the viable sigmoid used to form the abdominal colostomy in the Miles operation usually was long enough (1 cm) to be brought through the perineum. I have since transplanted to the perineum over 25 abdominal colostomies left after the Miles or other type of resection and these patients have found the perineal opening without sphincters to require less protection to be much more convenient to care for and less offensive from the escape of colonic gas than the previous abdominal colostomy.

It is desired to show iconographically by photographs of patients taken during immediately after and months and years after operation the marked advantages of the method of abdominoperineal proctosigmoidectomy now used. The entire rectum and lower half of the sigmoid is removed, tributary lymphatics are resected to a high level and the upper sigmoid is brought through the anus to unite spontaneously with the anal mucosa at the upper margin of the sphincters. The perineal part of the operation injures no important nerves or vessels and leaves a normal appearing and functional anus and perineum without the tendency to fistula or sinus formation or to mucous prolapse of the Hochenegg or other conventional posterior resections, in which the sphincters are preserved.

The defecation sense or warning that the lower bowel has filled and should be emptied often is present a few days after the operation. Voluntary contractions of the sphincters are produced at will, and nearly all of the patients after 4 to 8 weeks are able to dispense with a protective pad most, if not all of the time.

TECHNIQUE OF THE ABDOMINO-PERINEAL RESECTION

Before operation the usual laboratory studies are made, and sulfasuxidine is given at 4 hour intervals for 3 to 5 days. Laxatives and en-

emas are used unless there is complete or nearly complete intestinal obstruction when a catheter appendicostomy or cecostomy is formed through a small muscle-splitting incision, and the colon decompressed by irrigations every 2 to 4 hours with a 25 per cent glycerin solution or 10 per cent hydrogen peroxide. Parenteral feeding or transfusions are used before operation only for the very debilitated patient. The anesthesia is by spinal injection of 12 to 14 milligrams of pontocaine in 1 per cent solution to which largely to make it hyperbaric, 100 milligrams of procaine (novocain) is added. This is given through the first or second lumbar interspace, and the patient's head and chest are raised 10 degrees for the first 10 minutes, and then lowered. The analgesia usually lasts 2 to 3 hours. If Lemon's fractional method of spinal anesthesia is used it is desirable to inject a sufficient amount of the drug to prolong the anesthesia for an hour and to withdraw the needle just before the patient is put in position for the perineal part of the operation. In any case, an intravenous infusion is started immediately after the anesthetic is injected from 500 to 1000 cubic centimeters of 5 per cent glucose followed by 500 cubic centimeters of blood usually being given. For marked hypotension the head is lowered, and 1 per cent procaine containing 1 minim of epinephrine (1:1000) in each 10 cubic centimeters is freely injected about the wound field or rarely a few drops of dilute epinephrine solution are added to the infusion. With the exception of 1 patient with thousands of metastatic growths in his internal organs, in no case has sufficient shock or collapse developed to prevent the completion of the desired operation.

Abdominal phase The preferred abdominal incision runs parallel with and 3 centimeters above the left inguinal ligament (Fig 18) through the lateral edges of the sheaths of the left rectus muscle. The deep epigastric vessels are exposed divided and ligated and the peritoneum is opened. With this incision the strong oponeurotic layers rather than muscle are divided in the depths of the wound. Should more room be required, the median portion of the incision may be carried through one or both recti, and laterally the incision may be

lique. This anatomic incision gives satisfactory exposure and the undivided upper abdominal wall holds the small intestine and retentive pads in place better than with a vertical incision and rarely leads to a secondary hernia. If there is a lower median scar a vertical incision is substituted by excising the scar. The upper abdominal organs and finally the pelvic organs are explored by palpation. The left lateral peritoneal leaflet of the sigmoid is divided the left spermatic or ovarian veins are displaced laterally or divided and ligated and the left ureter recognized by its trombone-like movements on irritation is freed from the peritoneum nearly to the bladder. The peritoneal incision is continued lateral to the rectum to and then across the reflection of the bladder in men or the cervix in women. The hand is introduced from the left side under the attached bowel and mesentery from the great vessels and underlying sacrum to the coccyx any enlarged lymph nodes being particularly noted to the right of the bowel and along the elevated superior hemorrhoidal vessels. The inferior mesenteric vessels are doubly ligated with transfexion and divided below the left colic artery usually also the first sigmoid branch to enable the sigmoid curve to be straightened. The mesosigmoid is then divided to the bowel, usually between the first and second sigmoid arteries. Avoiding the ureter and sacral veins the peritoneum is divided well to the right of the rectum superior hemorrhoidal vessels and lymph nodes, and the incision is continued to the first peritoneal incision from the left side of the rectum. The lateral lower rectal vessels are then located and divided wide of the rectum, these vessels usually not requiring ligation. With the aid of a trowel and long scissors the rectum is separated from the vesical and prostate or in the female, from the upper vagina. The sigmoid proximal to its divided mesentery is now tested for vascularity by dividing small vessels on its surface and a sufficient viable length (12 cm) is liberated to reach from the sacral promontory through the pelvic floor. This may necessitate some mobilization of the lower part of the descending colon with division of its lateral peritoneal leaflet. A soft tape of folded gauze 1 meter long by 4 centimeters in width is tied about the sigmoid at the level of proved vascularity and the ends are packed back of the rectum against the floor of the pelvis. This gauze by pressure controls capillary oozing serves as a guide in the perineal phase of the operation and enables traction to be made on healthy, rather than cancerous bowel. The denuded pelvis is not peritonealized and a peritoneal pelvic diaphragm has been found unnecessary. Thus the bladder is not displaced over the intestinal coils after the rectosigmoid has been placed in the pelvis. The deeper layers of the abdomen are then closed preferably with interrupted layer sutures of No. 30 and No. 32 gauge stainless steel wire, which are tied in a square knot and the ends cut off very close to the knot. The skin and subcutaneous fat are united with interrupted No. 35 and continuous No. 38 stainless steel wire.

To remove blood and serous exudate from the pelvis during the early days after the operation, a perforated suction ("sump") drain (Fig. 18) 8 to 10 millimeters in diameter is carried on the left side of the bowel to the bottom of the pelvis and brought out through or near the lower angle of the incision. Low pressure aspiration of the inner tube of the drain is continued as by a small electric pump during the first 3 or 4 days after the operation. The intra abdominal sump drain empties the pelvis of fluid that may serve as a culture medium or diffuse bacteria. It also immediately indicates the onset of a postoperative hemorrhage, its degree persistence or arrest. It gives the earliest sign of ileus by a sudden aspiration of quantities of clear serum 24 to 40 hours before distention tympany and vomiting attract attention. Guided by this warning an aspirating indwelling duodenal tube is immediately introduced and often promptly relieves the obstruction. Likewise the drain will give the earliest indication of an infection in the depths of the pelvis by the odor and appearance of the material aspirated.

Perineal phase With the abdomen closed the patient is placed in the lithotomy position and the rectum is wiped out and packed with

ited with 3 5 per cent tincture of h the surrounding parts carefully a midline incision is made through r border of the anus, sphincters, o the right side of the coccyx (Figs. e pelvis, where the gauze attached oid is felt. The rectum is divided th scissors just above the sphunc but well below the carcinoma, and lge is caught as it is divided by a nostatic forceps (Fig 4) With gen- upon these forceps, and guided by ntroduced in the midline, the lev re elevated and cut laterally from and the urethra and prostate or separated anteriorly when the lib- um and sigmoid are easily withdrawn d is held apart by lateral retractors 7) The withdrawn bowel is wrap- owel and placed over the pubis on en With a trowel holding the sig ion against the pubis (Fig 8) the ity is sponged dry and any bleeding ligated The perineal wound is rela- scular and no ligatures may be re- the levatores ani are united in the 1 layers with No 31 gauge stainless interrupted sutures *without constric* e bowel (Figs 8 9) Otherwise, the swelling may strangulate the with- moid Omentum should not be trim- the bowel as they contain nutrient sels and occasionally a diverticulum.

The skin and fat are closed with fine (No 35 gauge) interrupted wire sutures (Fig 10) Af- ter the perineum has been closed it should be possible readily to introduce the finger between the bowel and sutured pelvic floor (Fig 11) Dressings are applied and the bowel is incised about 6 centimeters distant from the skin a No. 28 F rectal tube is inserted, and securely tied in with two encircling ligatures, and the rest of the bowel is cut away (Fig 12) A retention catheter is fastened in the bladder for the first 3 to 6 days, to be irrigated with boric or other solution daily It will be ob- served that the perineal floor is closed without drainage. With this technique less than 4 per cent have developed a perineal infection This is attributed to the iodine sterilization of the rectum and the exclusive use of stainless wire sutures and ligatures in this region As the withdrawn sigmoid is surrounded by a vascu- lar tube of anus and muscular pelvic floor to a depth of 5 to 7 centimeters, it is evident that the withdrawn bowel may slough back into the pelvic floor for several centimeters with- out ill effect. If there is question as to the sterility of the pelvic wound, a curved perfor- ated glass or metal drain or a large cigarette drain is to be inserted through the perineum to the anterior surface of the sacrum. With evi- dence of limited malignant invasion of the prostate or vagina, these should be resected. With irremovable extension into the base of the bladder and pelvic floor we have formed

the anal outlet as described with satisfactory palliation (Fig 16)

About 6 days after the operation the rectal tube will slough out of the bowel as a rule leaving a length of living bowel protruding from the anus (Figs 13, 16 17) Two to 6 days later, provided the perineal wound is well united, the redundant or protruding bowel is snared or burned off 1 or 2 centimeters beyond the skin by means of a heavy tonsil snare (Figs 14 15) or a clamp and galvanocautery. No anesthetic is required for this division as the bowel is insensitive. All bleeding should be controlled when the bowel is divided. The protruding end of the sigmoid soon spontaneously retracts and disappears within the anus, to unite with the edge of the anal mucosa just above the sphincters. If hemostasis is imperfect, bowel divided too close to the skin may retract too high and bleed back into the colon with exsanguination and no telltale escape of blood from the anus.

Seven to 9 days after the operation the patient is permitted to be out of bed and often will be in condition to leave the hospital on the eleventh to fourteenth day. At this time he will be able to contract his sphincters voluntarily and usually will have acquired a defecation sense. As a rule he will not be able to retain liquid or semiliquid sigmoid contents and should be instructed to take a quickly acting laxative such as sodium sulfate 8 grams in water 120 cubic centimeters, every second to fourth day, on arising. After 2 months (Figs 18 19) an enema or colonic irrigation may be substituted for the laxatives, used at intervals of from 2 to 5 days as determined by the personal habits of the patient. Except during periods of watery diarrhea, most patients then have little or no soiling and can dispense with a protective pad most or all of the time. The narrow annular scar uniting the sigmoid to the anal mucosa should be dilated frequently if it tends to contract. The patient may be given a set of test tubes or other dilators to be inserted daily after complete healing has occurred or instructed to insert a gloved finger until a permanent adequate opening has been established. A strictured opening will prevent complete evacuation and lead to colic and annoying dribbling. Eventually satisfactory

evacuation habits may be established for many patients without artificial aid or by the daily use of one or two teaspoonfuls of one of the bulk producing mucilaginous powders (metamucil, mucilose, kentos) derived from one of the varieties of plantain seed or other vegetable. Such powders are to be quickly stirred in a glass of cold water and drunk on retiring or arising. Other patients prefer an enema or quickly acting mild saline taken every 2 to 5 days. Even when cancerous invasion of the anus has made it necessary to remove the sphincters (Fig 24), the foregoing measures will render the perineal colostomy preferable to an abdominal colostomy provided an opening of sufficient caliber is maintained and the more troublesome laxative foods are eliminated from the diet.

It should be noted that the operation except for the removal of redundant bowel is performed in one stage, that no attempt is made to peritonealize the denuded pelvis that the sphincters are not denuded of their mucous membrane covering that the sigmoid withdrawn through the anus or pelvic floor is *not sutured* to the skin or other structures nor is the projecting portion cut away until at least 7 days have elapsed. Rhythmic longitudinal contractions continue in the withdrawn bowel causing holes or small contaminating fistulas if sutures are introduced and early and undesirable retraction when the bowel is cut flush with the skin. Minor modifications of the operation may be found desirable. Formerly I used a fairly large perforated glass or rustless steel tubular drain in the perineum instead of an abdominal sump but an occasional serious perineal infection occurred attributed to the open drained wound in an area difficult to protect adequately from soiling. For those inexperienced or who use catgut in the perineum I would advise pelvic drainage by tube or a large cigarette drain. My colleague Dr H E Bacon divides the anal mucosa close to the skin margin and dissects it from the sphincters. This procedure enables the denuded sphincters to be stretched sufficiently for the withdrawal of the rectosigmoid and a week or more later when the protruding bowel is trimmed back he sutures the margins to the skin edges with catgut. Unless the sphinc

The Paul Mikulicz operation particularly for the rectosigmoid is insufficiently radical, has a higher operative mortality,¹ a greater morbidity, and the highest incidence of recurrence in the abdominal wall adjacent bowel and mesentery, and of secondary hernia. However, if the bowel ruptures or is perforated, it provides the quickest way to terminate the operation. I have not used this method or its modifications in the last 3 years.

For some years I have been practicing radical excision without colostomy for inoperable carcinoma of the large bowel. In this way a considerable proportion of patients with inoperable carcinomas have had the primary growth removed and have lived longer and more comfortably than if a palliative colostomy had been done. Of the last 300 patients seen only 3 per cent were considered to have disease too far advanced for palliative resection. Several had had a colostomy which also was eliminated. About 20 per cent had secondary palpable growths in the liver and 13 per cent had extension of the cancer to other abdominal organs, yet most of these patients, after radical resection with primary wound closure, lived from 7 months to several years in improved health.

Hospital mortality. In a personal experience of 617 radical operations for cancer of the large intestine the mortality has markedly decreased with experience, improvements in technique, and the routine use of antibiotics. Of the last 300 patients entering my service, 97 per cent (aged from 21 to 87 years) have had radical intestinal resection. A number of these had a previous colostomy without extirpation of the cancer. Three per cent had disease so advanced that even a palliative operation was

considered of no advantage. Ninety seven per cent, about one-third with advanced and inoperable malignancy, had a radical resection of the cancerous bowel, with a hospital mortality of 9 per cent. However, in the series there were 66 consecutive radical operations with 1 death, and in a rather recent series of 100 admissions for carcinoma of the large bowel, 2 were found to have disease too extensive for resection or colostomy, with 1 hospital death. Ninety-eight had radical resection, including 18 with palpable metastatic carcinoma of the liver and 13 with cancerous invasion beyond the bowel. Three with carcinoma of the anus had perineal resection with perineal colostomy, without mortality. Forty four had the abdominoperineal operation with retained anus, with 2 hospital deaths (1 with advanced carcinoma of the liver), a mortality of 4.5 per cent. 51 had one stage, abdominal, aseptic, end-to-end resections with 2 hospital deaths (3.9 per cent), 1 from coronary occlusion, 1 from peritonitis. Sixteen of these 51 end-to-end resections were for cancer of the rectum, 22 for cancer of the sigmoid or descending colon and 13 for cancer of the right or transverse colon.

GNOSIS IN CARCINOMA OF THE COLON AND RECTUM

A 10 Year Follow Up of 337 Patients

BENTLEY P. COLCOCK, M.D. Boston, Massachusetts

Is a well known but occasionally forgotten fact that the term "five year cure" is little more than a convenient yardstick when used in connection with patients ring from malignant disease. It will give approximate idea of the end-results in a p of patients with malignant disease in site or another but it cannot be applied to individual patient. Some of these people who have survived 5 years following the oval of their cancer will ultimately die of r original disease. This is true of carcinoma of the colon and rectum just as it is of anoma of the breast and other viscera. It f interest and of value to know the results these patients with carcinoma of the colon l rectum 5 years after operation and what chances are for an individual patient with malignant lesion to live not only 5 years t 10 or more years following resection of the dignant tumor.

In 1929, Jones reported a 22.7 per cent mortality in a series of 204 cases of carcinoma of rectum in which the patients were treated abdominoperineal resection. Seventy per nt of the patients who survived operation re alive and well at the end of 3 years and 3 per cent were living 5 years after their eration. His operability or resectability te was 53 per cent.

Miles, in 1931 followed a group of 94 patients who had survived abdominoperineal rection for carcinoma of the rectum, and found 9 alive and well at the end of 5 years. This is a 5 year nonrecurrence rate of 73.3 per cent.

Abel in 1935 found a 69.2 per cent survival ate in 150 patients whose course was followed or 5 years following abdominoperineal resec on for carcinoma of the rectum. These figures are somewhat higher than those found in his country.

In 1933 Rankin in a follow up of 300 patients who had had resection for carcinoma of

From the Department of Surgery, The Lasey Clinic.

the rectum, found a 5 year survival rate of 48 per cent in those patients who showed no metastasis to lymph nodes in the resected specimen. In the group of patients in whom the lymph nodes were involved 20 per cent survived 5 years. In 187 cases of carcinoma of the right colon Rankin and Olson obtained 5 year cures in 39 per cent of their patients with nodal involvement, and in 66 per cent of those without nodal involvement. In 266 cases of carcinoma of the left colon their figures were 29 per cent and 56 per cent, respectively.

In 1943 Cattell found 53.6 per cent of 140 patients who had survived resection for carcinoma of the colon or rectum were living 5 years or more after operation. This figure was based on all patients submitted to resection and included palliative operations and unfavorable resections as well as favorable cases. It is of great value to know the operability or resectability rate in evaluating statistics relating to end results, for in any group of cases if the patients with unfavorable lesions are not submitted to resection the survival rates naturally will be higher. The operability rate in this group of patients was 83.5 per cent.

In 1943 Mayo and Twyman followed 79 cases of carcinoma of the rectum and found that 70.9 per cent of the patients with favorable lesions and 45.5 per cent of those with unfavorable lesions were alive and well 3 years after operation. In 1945 Hayden in reviewing 198 patients with carcinoma of the rectum who were submitted to resection found a 5 year cure rate of 33 per cent among the 98 patients whose course was followed for 5 years or more. His resectability rate was 80.6 per cent for all patients seen and 88.0 per cent for the group who came to operation.

The spread of carcinoma of the colon or rectum through the adjacent lymphatics has long been understood. For many years we have routinely isolated and examined the mes-

entent lymph nodes in each resected specimen for the presence of metastatic carcinoma. The significance of nodal involvement to the prognosis in the individual case is apparent from the present study and from the cases reported in the literature. Only in recent years however has the frequency with which carcinoma of the colon and rectum may spread through the vascular system been fully appreciated. Any discussion of prognosis following resection for carcinoma of the colon and rectum should emphasize the seriousness of blood vessel invasion as seen in the microscopic examination of the resected specimen. In one study of 208 patients we found that of those patients who had shown blood vessel invasion at the time of operation only 15 per cent were alive 5 years later.

In the present study the case histories of 337 patients with carcinoma of the colon and rectum were carefully reviewed. All were treated prior to 1936 and 307 of these patients have been followed for at least 10 years.

The patients were divided into two main groups. In the first group were those with carcinoma of the colon including carcinoma of the cecum ascending transverse descending and upper sigmoid colon. The second group consisted of patients with carcinoma of the lower sigmoid rectosigmoid and rectum since in these cases some type of resection of the rectum and rectosigmoid with the establishment of a proximal colostomy, was carried out.

CARCINOMA OF THE COLON

There were 103 patients with carcinoma of the colon. The youngest patient was 27 years of age the oldest 74 and the average age was 57 years. The incidence of carcinoma of the colon was slightly higher in women (56) than in men (47) whereas the reverse was true for carcinoma of the rectum.

Eighty-one of the 103 patients were submitted to some type of resection including 14 palliative resections. This is a resectability or operability rate of 78.6 per cent. Three of the palliative resections were definitely so because of the presence of liver metastases at the time of operation and 11 others were considered so because of local invasion at the time of resection. There were 22 patients in whom resec-

tion was not considered feasible. Three patients were not operated on, 4 had laparotomy only, 2 had cecostomy and 13 had a side tracking anastomosis such as an ileotransverse colostomy or colocolostomy.

A modified Mikulicz type of resection was done in 76, or 94 per cent of the patients submitted to resection. A two stage resection consisting of a preliminary anastomosis followed by resection subsequently was done in 4 and a one stage resection with primary anastomosis was performed in 1 case. A tendency toward a one stage procedure for resection of carcinoma of the right colon is shown by the comparison of these figures with those for 1945 when a one stage procedure with primary anastomosis was carried out in 17 per cent of patients with carcinoma of the cecum ascending colon and hepatic flexure. In the remainder a modified Mikulicz type of resection which we still prefer for carcinoma of the left colon, was performed. The modified Mikulicz procedure has two distinct advantages over other two stage procedures. In the first place it removes the growth at the primary operation and at the same time avoids an intraperitoneal anastomosis, and in the second place the second stage is an extraperitoneal type of procedure.

Mortality Five deaths occurred in the group of patients in whom the malignant tumor was limited to the bowel wall. Eight deaths occurred in the group in which the carcinoma already had invaded either the adjacent lymph nodes or neighboring viscera. This is a mortality of 16.0 per cent in the resected cases. In line with the marked reduction of the mortality noticed in all surgical centers interested in the treatment of carcinoma of the colon it may be noted that the mortality in this group of patients in 1945 was 2.3 per cent. This has been accomplished in spite of the fact that the operability rate has continued to rise and in 1945 was 90.7 per cent. Three deaths occurred among those patients in whom only laparotomy or a palliative anastomosis was possible.

Follow-up In the group in which the regional lymph nodes and adjacent viscera were not involved there were 38 patients in whom the 10 year follow up was complete. Of this group 5 patients died in the hospital 5 other

TABLE I—CARCINOMA OF COLON

Type of operation	Hospital deaths	Patients dying of carcinoma following operation							Living and well 10 or more years	Deaths from other causes	Total
		1-6 mos.	6-12 mos.	1-18 mos.	18-24 mos.	24-36 mos.	3-5 years	5-10 years

*Nodules noted in liver at time of operation; biopsy not done and may not have been metastases.

patients subsequently died from causes other than recurrences of the carcinoma. These patients had lived from 3 months to 8 years following operation with no evidence of recurrence at the time of death from other causes.¹ Of the remaining 28 patients, 18 were living and well at the end of 5 years, 2 died of recurrent malignant disease between their fifth and tenth postoperative years, and 16 were living and well 10 or more years following resection of their malignant lesion. In 12 additional cases the 10 year follow up was incomplete although 6 of these 12 patients are known to have been living and well 5 or more years after operation. Thus, in the group of patients who survived operation and in whom the 10 year follow-up is complete, the 5 year survival rate is 64.3 per cent and the 10 year survival rate is 57.1 per cent.

Of the 27 patients in whom the malignant disease had extended to the adjacent lymph nodes or involved the surrounding structures, 8 died in the hospital and 15 died of recurrence of their disease within 5 years (Table I). One patient died of a recurrent carcinoma after having survived 5 years and 3 patients are living and well 10 or more years after operation. Thus, for this unfavorable group the 5 year survival rate has dropped to 14.8 per cent and the 10 year survival rate to 11.1 per cent. One patient with sarcoma of the colon

died less than 18 months after operation from recurrence of his malignant disease. Four patients in whom resection was done in the presence of liver metastases lived from 1 to 5 years following operation. In the one case in which the patient survived more than 3 years, there is some question as to whether the nodules noted in the liver at the time of operation were actually metastases, since no biopsy specimen was obtained. Of the 4 cases in which laparotomy only was performed, not 1 patient survived a year. The same was true for the 13 patients in whom only a sidetracking anastomosis was carried out.

CARCINOMA OF THE RECTUM AND RECTOSIGMOID

There were 234 patients with carcinoma of the rectum and rectosigmoid. Of these 129 were males and 105 were females. Their ages ranged from 21 to 75 years, with an average age of 57 years. It is worth while to note again that carcinoma of the rectum is found not uncommonly in patients under the so-called cancer age. Nineteen patients or 8 per cent of the entire group were under 40 years of age.

Procedure. One hundred forty-six patients, or 62 per cent of this group were submitted to some type of resection. A two stage Lahey procedure was performed in 83 or 56.8 per cent of the 146 patients, a one stage abdominoperineal (Miles) resection in 24 or 16.4 per cent, a posterior resection in 22 or 15.0 per cent, and an anterior resection (with permanent colostomy) in 17 or 11.6 per cent. Eighteen of these resections were considered palliative. 11

¹Since these figures are being examined from the point of view of recurrence or nonrecurrence of carcinoma of the colon and since those patients who die from other causes represent an unknown quantity in this respect, it seems reasonable that they should be excluded in the final analysis. It is important, however, to know the number of these patients and the length of time after operation when death occurred. A patient should be excluded who was not free of all evidence of recurrence at the time of death.

TABLE II—CARCINOMA OF RECTUM AND RECTOSIGMOID

Type of operation	Hospital deaths	Patients dying of carcinoma following operation							Living and well 10 or more years	Deaths from other causes	Total
		<6 mos.	6-12 mos.	13-18 mos.	19-24 mos.	25-36 mos.	3-5 years	5-10 years

Resection, liver negative lymph nodes negative	6		3	1		2		5	31	7	73
Sarcoma											

definitely so because of the presence of liver metastases and 7 probably so because of invasion of adjacent structures. A steady tendency toward the increasing use of the one stage Miles abdominoperineal resection is shown by the fact that this procedure was used in 16.4 per cent of the above group, 76.7 per cent in the year 1941, and 97.5 per cent in 1945. Resection was not carried out in 88 cases, a colostomy having been done in 62, a first stage Lahey procedure in 10, and a laparotomy only in 11. No operation was performed in 5 cases.

Mortality. Of the 146 patients who were submitted to resection, including 18 palliative resections, there were 11 deaths, or a mortality for the resected cases of 7.5 per cent. Since 1936 the operative mortality for carcinoma of the rectum has dropped to 3.8 per cent in 1941 and 6.2 per cent in 1945. At the same time the operability rate has increased from 62 per cent to 83 per cent.

Twenty-eight deaths occurred in the group of patients whose growths were so extensive that only laparotomy or colostomy was possible.

Follow-up (Table II). In the group of 73 patients in whom there was no evidence of involvement of the liver or lymph nodes at the time of resection, 31 patients are known to be living and well 10 or more years following their operation. At the end of 5 years following operation, 36 patients were living and well without evidence of recurrence. Five patients died from recurrence of the carcinoma between their fifth and tenth postoperative years. Twenty-four patients died from recur-

rent carcinoma in from 1 month to 5 years following operation. Seven patients subsequently died from other causes, with no evidence of recurrence at the time of their death. (5 of these 7 patients had survived without recurrence 4½ to 7 years after their resection.) There were 6 postoperative or hospital deaths. The 1 patient with sarcoma of the rectum died from recurrent malignant disease less than 18 months after his operation. Omitting the 6 postoperative deaths and the 7 patients who died from causes other than the recurrence of their carcinoma, the 5 year survival rate is 60 per cent and the 10 year survival rate is 51.6 per cent.

In 52 cases no metastases were noted in the liver at operation, but the carcinoma was found to have spread to the mesenteric lymph nodes on examination of the resected specimen. Of this group, 10 patients are living and well 10 or more years following their operation. Three patients died from a recurrence of their malignant disease between their fifth and their tenth postoperative years. There were 5 postoperative deaths and 4 other patients subsequently died from other causes with no evidence of recurrence at the time of their death. Omitting the postoperative deaths and the patients who died from other causes than malignant disease, the 5 year survival rate is 30.2 per cent and the 10 year survival rate is 23.2 per cent.

In the entire group, 28 patients died of their disease within 6 months of operation. Of these, 25 or over 89 per cent occurred in the group in whom only laparotomy or colostomy was possible. Thirty patients died of the

TABLE III.—CARCINOMA OF COLON

Group	Percentage of patients living and well for 5 years	Percentage of patients living and well for 10 years
Unfavorable (lymph nodes involved and local invasion)	3	
Favorable (lymph nodes not involved)	64.3	57.4

TABLE IV.—CARCINOMA OF RECTUM AND RECTOSIGMOID

Group	Percentage of patients living and well for 5 years	Percentage of patients living and well for 10 years
Unfavorable (lymph nodes involved and local invasion)	30	23
Favorable (lymph nodes not involved)	66	51.5

disease in 6 to 12 months after operation. In 16 or 53.3 per cent resection was not possible, and in an additional 16.6 per cent liver metastases had been noted at the time of the palliative resection. Although there was no difference in the length of survival of patients who had resection of their growth in the presence of liver metastases and those who had colostomy only (only 1 patient in each group lived more than 3 years) there was a marked difference in the postoperative clinical course. Those patients in whom the rectal lesion was left *in situ* were usually very uncomfortable from the constant discharge of mucus and blood from the rectum, and they often had severe pain from sciatic and perineal nerve involvement. Those patients in whom the primary growth was removed were usually comfortable until within a few weeks of their death.

Of the 15 patients in whom the 10 year follow up was incomplete and who were not included in the above analysis 6 patients had had such advanced disease that only a laparotomy or colostomy was possible at the time of operation. Three other patients had resection in the presence of metastasis to adjacent lymph nodes or local extension of the growth.

Thus, of the resected cases not known definitely to be palliative or unfavorable only 6 were not followed for 10 years and 5 of these are known to have been living without recurrence 6 to 8 years after operation.

SUMMARY

The case histories of 81 patients who had resection for carcinoma of the colon 10 or more years ago were carefully reviewed. Of the patients with favorable lesions that is those in whom the adjacent lymph nodes were not involved and there was no local invasion of the surrounding tissues, 64.3 per cent survived 5 years without recurrence and 57.1 per cent are living and well without recurrence 10 or more years following resection of their malignant tumor.

Of the patients with unfavorable lesions, that is those in whom the lymph nodes showed evidence of metastases or there was invasion of the surrounding structures by the tumor 15 per cent were living and well 5 years

after operation. Eleven per cent are living and well 10 or more years following resection (Table III).

The histories of 146 patients who had had a radical resection for carcinoma of the rectum or rectosigmoid 10 or more years ago were also reviewed.

In the favorable group (adjacent lymph nodes negative for carcinoma, no local invasion) 60 per cent were found to be well with out recurrence at the end of 5 years; at the end of 10 years this figure had dropped to 51.6 per cent.

In the less favorable group (lymph nodes showing metastatic carcinoma or invasion of the surrounding tissues by carcinoma) 30.2 per cent survived 5 years without a recurrence. Only 23.2 per cent are living and well ten or more years following their operation (Table IV).

Of the patients who died from malignant disease between the fifth and tenth postoperative years the majority died between 5½ and 6½ years following operation. Two patients lived 7 years and one 8 years. All of these patients gradually failed and died with the signs and symptoms of carcinomatosis of the abdominal cavity. Nevertheless, the possibility exists that some in this group may have succumbed to a second undetected primary lesion arising in the gastrointestinal tract and not as the result of a recurrence of their resected lesion.

COLCOCK PROGNOSIS IN CARCINOMA OF COLON AND RECTUM

CONCLUSIONS

These figures suggest that in a patient with carcinoma of the rectum in whom the mesenteric lymph nodes of the resected specimens show no evidence of carcinoma, the prognosis is approximately twice as favorable as it is for a patient in whom the lymph nodes are positive. The unfavorable significance of positive lymph nodes in carcinoma of the colon appears even greater.

The figures also suggest that, although some patients who are living 5 years after resection for carcinoma of the colon or rectum will ultimately die of their disease, more than 50 per

cent of those who survive this operation in whom the mesenteric lymph nodes are negative for carcinoma may expect a permanent 'cure' of their malignant disease from cal surgical resection.

CONGENITAL ATRESIA OF INTESTINE AND COLON

WILLIS J. POTTS, M.D., F.A.C.S., Chicago, Illinois

THE outlook for newborn infants with congenital atresia of the bowel is not as black as it was 20 years ago. Up to that time a postoperative recovery was of sufficient rarity to be worthy of publication. Because of persistent work by those interested in children's surgery—Ladd and Gross, Miller, Donovan, Duckett, Webb and Wangenstein and others, the mortality figures are constantly improving. The infant who does not come to surgery until the intestines have ruptured and produced a full-blown peritonitis has little or no chance of survival. Likewise, the infant with multiple anomalies of the bowel or severe associated congenital malformations has a very slim chance of surviving surgery. The prognosis is good, however, for a full-term infant who is normal except for atresia of the bowel and who is operated upon the third or fourth day of life. Earlier diagnosis, chemotherapy and use of more appropriate suture material have contributed to a higher percentage of recoveries.

During the past 6 months, 5 patients with congenital atresia of the bowel have come under my care and have been operated upon: 1 of the duodenum, 3 of the ileum and 1 of the colon. There was 1 death.

DIAGNOSIS

Little difficulty would be experienced in making a diagnosis if congenital atresia of the bowel were more common. However, many physicians in general practice never encounter this condition in a lifetime of active practice. Even in the practice of a busy pediatrician few of these patients are seen. It is entirely probable that the diagnosis is not made until the symptoms of intestinal obstruction present themselves.

Vomiting is the outstanding early symptom. It begins the first or second day after birth, depending upon the level of obstruction and is

persistent. By the third day of life the vomitus is greenish brown and has a foul odor. The majority of atresias are below the ampulla of Vater and the vomitus contains bile. In Case 1 of this series the obstruction was above the ampulla.

Distention varies with the level of obstruction. In Case 4 of an infant with atresia of the colon there was tremendous distention where as the infant with atresia of the duodenum after deflation of the stomach had a scaphoid abdomen. Gastric peristaltic waves passing from left to right are seen in babies with duodenal atresia. Intestinal patterning is easily visible in patients with lower obstructions.

The difference in the stool of an infant with atresia of the bowel and that of a normal infant is recognizable but not impressive. It is light green, very small in amount and contains mucus in contrast to the tarry appearance of a normal meconium stool. Farber's test is of value if uncertainty exists.

Röntgenologic examination is of great help in establishing the diagnosis (Figs. 2, 3, 4, 5, and 6). The roentgenogram should be made with the infant in the upright rather than the supine position. If obstruction is present, widely distended loops of bowel showing fluid levels will be seen. Furthermore, the x-ray film will indicate whether the obstruction is high or low. Positive differentiation of duodenal, ileal or colonic obstruction is impossible because of the enormous dilatations seen and because these loops crowd one another into abnormal positions. The administration of barium to these babies is condemned. Its use is unnecessary to make a diagnosis of obstruction; it clogs the intestine and if aspirated tends to produce pneumonia.

A general physical examination is important primarily as a search for other abnormalities. A rectal examination is in order to determine patency.

PREOPERATIVE CARE

Parenteral fluid is essential for these infants who usually are admitted in a state of

Fig 1 Operative technique (see text)

moderate dehydration. Fluids can be given most satisfactorily by the intravenous route with a cannula in the saphenous vein at the ankle. A "cut down" is always necessary for insertion of the cannula. Administration of fluid by "marrow infusion" with a Tocantini needle may be used but is inferior to the intravenous method. Isotonic solution of saline 10 to 15 cubic centimeters per pound of body weight each 24 hours is sufficient. Dextrose solutions in 5 to 10 per cent concentrations should be used to bring the total fluid intake for 24 hours up to 50 to 75 cubic centimeters per pound of body weight. The fluid is begun preoperatively and continued postoperatively. Small blood transfusions 50 to 75 cubic centimeters and plasma are used as indicated.

The stomach must be completely emptied before operation. A No. 10 F catheter is in-

serted into the stomach through the nose and all fluid removed by suction with a syringe. If this material in the stomach is thick, or if the infant has been given barium, lavage may be necessary with a measured amount of water all of which is removed. The catheter is left in place during operation and postoperatively attached to a Wangenstein suction apparatus.

OPERATION

Drop ether with an open mask is most satisfactory. A longitudinal right rectus muscle splitting incision is made sufficiently long to allow for adequate exposure. The greatly distended loops of bowel are allowed to escape from the abdominal cavity. There will be far less trauma to the fragile bowel wall if it is allowed to protrude as it will and is covered with moist packs.

SURGERY GYNECOLOGY AND OBSTETRICS

The collapsed undeveloped bowel distal to the obstruction is ordinarily the size of an old fashioned slate pencil (Fig 5). It is followed downward in a quick search for other points of atresia. Then with a fine hypodermic needle salt solution is injected into its lumen just beyond the site of atresia to demonstrate other points of obstruction that may have been overlooked. If the fluid can be followed to the rectosigmoid patency has been demonstrated. A large caliber needle attached to a 50 cubic centimeter syringe is inserted into the distended bowel at a point where the incision is to be made later for the anastomosis. The introduction of the air and meconium allows the thin bowel wall to collapse, makes the anastomosis easier and lessens the danger of leakage through needle punctures.

A side-to-side anastomosis is done between the proximal and distal loops (Fig 1). Whether the anastomosis is made isoperistaltic or anti-peristaltic seems to make little difference. The loops of bowel are apposed by two interrupted stitches of silk one at each end of the site of the proposed anastomosis. These sutures are used to steady the loops of bowel while serosa is sewed to serosa with a continuous over and over silk stitch. No 00000 Deknatel braided silk on a curved No 9 atraumatic needle is the suture material of choice. The fact that the swaged-on needle is very fine, almost the same size as the silk, minimizes the danger of suture leakage. A fairly long cut is made in each loop of bowel. Mucosa is sewed to mucosa with the running over and over stitch on an atraumatic or No 00000 chromic catgut on an atraumatic needle. It is judicious to take small bites of bowel wall in each stitch lest the lumen be encroached upon. It is my feeling that a running over and over suture carefully placed gives a better seal than interrupted stitches and that it interferes less with the mattress suture. A second interrupted silk stitch at each angle re-enforces and completes the anastomosis. The opening in the mesentery is closed by multiple atresias exist the intervening segments may or may not be resected depending upon the condition of the patient. If left they will eventually produce sausage-shaped cysts requiring removal.

Usually a transfusion of 40 to 60 cubic centimeters of citrated blood is given during the operation.

The operative wound in each instance is closed with No 000 chromic catgut for the peritoneum and posterior sheath of the rectus. The anterior sheath of the rectus is closed with interrupted No 0000 Deknatel silk sutures.

POSTOPERATIVE CARE

Upon return to the crib the infant is given 50 000 units of penicillin followed by 10 000 units every 3 hours thereafter. A Wangenstein suction apparatus is attached to the catheter in the stomach immediately after operation and suction continued for 48 hours. Every 4 to 6 hours the catheter is irrigated with a medicine dropper to be sure that suction is being maintained. The necessary amounts and types of fluid are continued intravenously. On the third postoperative day the catheter and suction apparatus are removed and the routine postpyloric regimen of feeding is begun. It is very important to underdo rather than press the amounts of food given. In Case 2 overfeeding necessitated resumption of gastric suction for 48 hours. By the seventh to fourteenth day if all goes well the infant is usually on a maintenance diet.

CASE REPORTS

CASE 1. J. B., a baby girl, was born May 26, and referred to The Children's Memorial Hospital by Dr. Edna Mortimer, weighed 5 pounds 7 ounces at birth and 4 pounds 11 ounces upon admission. Physical examination revealed a tiny somewhat dehydrated infant with small mongoloid eyes deeply jaundiced. X-ray examination by the roentgenologist in the upright position showed two large fluid filled, Dr. Aspasch revealed. Films made with the patient in the upright position typical of high obstruction of the duodenum (Fig 2).

Operation. The stomach and first part of the duodenum proximal to the ampulla of Vater were greatly distended. The rest of the bowel was tiny and collapsed. Since the duodenum could easily be raised for its third portion could easily be raised for its third portion. This was accomplished by two rows of continuous silk sutures. Immediate postoperative condition was good. The second postoperative day continuous feedings were begun, well tolerated and retained. Normal bowel move-

Fig. 4. Case 3. Roentgenogram shows loops of dilated small bowel.

Fig. 5. Case 3. Characteristic findings at operation—single atresia of the ileum.

ments were passed. For 6 days the infant did well even gained a little weight and then died suddenly. Postmortem examination revealed no demonstrable cause of death. There was a patent foramen ovale, a few petechial hemorrhages in the lungs and some congestion of all the organs. The duodenoduodenotomy was intact and in the normal process of healing. The presumptive cause of death was suffocation.

CASE 2. K. M., a baby girl was born June 25 and referred to The Children's Memorial Hospital June 30 by Dr. Ina Harper of Benton Harbor, Michigan. The infant's weight at birth was 6 pounds 8 ounces, upon admission 5 pounds 11 ounces. She had vomited all feedings since birth and had passed no meconium. Her general condition was fair and a good state of

hydration had been maintained. Her abdomen was distended and intestinal patterning was visible. An x-ray film of the abdomen revealed distended loops of small bowel containing barium. Diagnosis was congenital atresia of the small bowel (Fig. 3).

Operation. An enormously dilated bluish purple but not gangrenous ileum was exposed. The obstruction was single about 6 inches proximal to the ileocecal valve. A side-to-side antiperistaltic anastomosis was done with two rows of continuous silk sutures.

The infant passed tarry meconium the first postoperative day. We disregarded our own advice to underfeed these infants. Abdominal distention and vomiting on the eleventh postoperative day necessitated the reinstitution of continuous gastric lavage.

Fig. 6. Case 4. Anteroposterior and lateral roentgenograms showing tremendous dilatation of the ascending colon.

and parenteral fluids for 48 hours. Feedings were then begun cautiously and were well retained. The infant was discharged in good condition on the twenty-second postoperative day.

CASE 3. F S, a baby boy was born August 1 and referred to The Children's Memorial Hospital August 3 by Dr. Eugene T. McEnery. His weight at birth was 6 pounds 5 ounces upon admission 6 pounds. The infant had vomited persistently since the second day after delivery. His general condition was good. The abdomen was distended and showed intestinal patterning. X-ray examination revealed distended loops of bowel with fluid levels (Fig. 4). Diagnosis was congenital atresia of the small bowel.

Operation. Single atresia of the ileum was found 1 inch above the ileocecal valve (Fig. 5). An isoperistaltic side-to-side anastomosis was done about the obstruction using No. 0000 silk on the serosa, and No. 0000 chromic gut on the mucosa. The child made an uneventful recovery and was discharged on the eighteenth postoperative day.

Fig. 7. Case 4. Diagrammatic illustration of operative findings in congenital atresia of the transverse colon.

Fig. 8. Case 5. Anteroposterior and lateral roentgenograms showing huge dilatation of the small bowel in congenital atresia of the ileum.

CASE 4. B M, a baby girl, was born August 22, and was referred to The Children's Memorial Hospital August 25 by Dr. John A. Bigler. Her weight at birth was 7 pounds 8 ounces upon admission 6 pounds 5.00 oz. Persistent vomiting had begun 48 hours after delivery. Upon admission the abdomen was greatly distended and tympanitic. X-ray examination revealed a collection of air and barium containing fluid in the right half of the abdomen (Fig. 6). This was erroneously interpreted by us as a rupture of the bowel because it seemed impossible that dilatation to such size could occur without rupture. Preoperative diagnosis was congenital atresia of the ileum with rupture. Postoperative diagnosis was congenital atresia of the transverse colon without rupture.

Operation. When the abdomen was opened the unruptured, ascending colon delivered itself from the wound. Complete atresia of the transverse colon was found just beyond the hepatic flexure. The distal colon was patent. The ascending colon resembled a toy balloon, the transverse and descending colon a long angieworm. A side-to-side isoperistaltic anastomosis was performed.

Fig. 9. Case 5. Operative findings. The tip of the for ceps indicates the second point of atresia demonstrable only after injecting the bowel with salt solution.

stomosis was done using No 00000 silk throughout (Fig 7). The postoperative course was singularly smooth. On the nineteenth postoperative day a barium enema demonstrated that the lumen of the colon had enlarged considerably. The infant was discharged in good condition on the eighteenth postoperative day.

CASE 5 J P a girl was born October 13 and was referred to The Children's Memorial Hospital October 18 by Dr Anders J Weigen. She weighed 6 pounds 15 ounces at birth and 6 pounds 4 ounces upon admission. Vomiting had begun on the second day of life and persisted. The vomitus upon admission had a fecal odor. No bowel movement had been passed since birth. Hydration had been well maintained and the infant's general condition was surprisingly good. X-ray examination revealed an enormous dilatation of the small bowel (Fig 8).

First operation October 18 1946 Atresia of the ileum at approximately its midportion was found. Injection of salt solution into the ileum distal to the obstruction revealed a second atresia about 8 inches from the first (Fig 9). It had not been seen upon exploration. This 8 inch section of bowel was removed and the ends turned in with interrupted silk sutures. A side-to-side isoperistaltic anastomosis was done, using No 00000 silk for the serosa and No 0000 chromic catgut for the mucosa. During and immediately following the operation 75 cubic centimeters of citrated blood was given. Postoperatively the child did well for 9 days. Then distention and vomiting recurred and persisted in spite of continuous gastric aspiration.

Second operation November 1 1946 The previous incision was opened and a generalized subdiaphragmatic peritonitis was found. Large collections of yellowish turbid fluid were aspirated. The loops of bowel were plastered together with masses of plastic exudate. There was no odor. Exposure to the anastomosis did not seem justified because of the amount of trauma it would entail. The abdomen was closed without drainage. Streptomycin 50,000 units every 3 hours was started postoperatively along with 10,000 units of penicillin which the infant has been

receiving since the first operation. A number of bowel movements were passed and feeding again cautiously begun. For a week the infant did well. Distention recurred and again continuous aspiration of the stomach failed to relieve it.

Third operation November 15, 1946 The old incision was reopened but in spite of care a hole was made in the distended bowel adherent to the anterior abdominal wall. The hole in the bowel was closed with interrupted silk sutures. Exploration revealed obstruction cause undetermined, at the site of anastomosis. A side-to-side antiperistaltic anastomosis was made about the previous one and the abdomen closed. The third postoperative course was uneventful. Small feedings started on the third day following operation were retained and well tolerated. At the time of writing the infant is taking a generous diet and is gaining weight.

CONCLUSIONS

Earlier diagnosis chemotherapy proper suture material and physiological preoperative and postoperative care have improved the outlook for infants with congenital atresia of the bowel.

Five cases of atresia of the bowel with 1 death are reported.

Review of medical literature indicates that the patient with congenital atresia of the transverse colon included in this report is the first to survive surgery.

DOUBLE CLEFTS OF THE LIP

JAMES BARRETT BROWN M.D., F.A.C.S. FRANK McDOWELL, M.D. F.A.C.S., and
LOUIS T. BYARS M.D. F.A.C.S. St. Louis, Missouri

THE surgical repair of double cleft lips is about twice as difficult as in single clefts and the results are about half as good. Nevertheless, enough slow progress has been made to be worth recording and to note procedures or details to avoid

Normally the frontonasal process of the embryo fuses with the two lateral maxillary processes by the ninth week. When there is total lack of fusion of these on both sides, the three processes develop independently of each other from the ninth week until term with the result that the baby has not only a hiatus or cleft on either side, but also has severe growth distortions of the entire middle third of the face. Partial fusion on one side makes this distortion asymmetrical on the two sides and may render the interpretation and plan for repair even more difficult.

Many of the surgical principles and operative details outlined in previous papers on single cleft lips (1-2) are applicable in double clefts and will be referred to frequently. The double clefts however vary a great deal more in the amount and shape of the deformity so that more individual study and improvising is necessary in planning their repair. They are not considered surgically simply as two single clefts both of which happen to occur in the same patient.

AGE FOR PRIMARY OPERATION

The child with a double cleft lip has a very difficult feeding problem, produces much psychic shock to the parents and incites so many exclamations of curiosity and pity from others that an early closure is necessary (Figs. 1-6). It may be true that nicer closures could be obtained in some of these patients with less difficulty by waiting (Figs. 13-14) but the situation in general is almost intolerable for both the parents and the child. The operation is one of considerable magnitude though and

they are not closed as early as single clefts. A fairly satisfactory rule is to close them as soon as possible after the baby weighs 10 pounds subject to variations in the extent of the deformity and the child's general physical condition. Many of these patients have an anemia and are given transfusions to bring the preoperative hemoglobin up to 12 to 15 grams per cent. Nearly all of those with open palates will have a chronic otitis media which is not an especial contraindication to surgery. Operations are not done of course during an acute exacerbation.

Until the lip is closed feeding is done with a syringe (with a short piece of rubber tubing attached) and gavage is usually avoided.

TREATMENT OF THE PREMAXILLA

The premaxilla is the separate central segment of the upper jaw and is that portion arising from the embryonic frontonasal process. Briefly the problem of the premaxilla is that it is nearly always too far forward in the newborn baby but only with considerable effort can it be kept from being retruded too far backward in the adult. It varies a good deal in size, shape and position and at times as to the number of tooth buds it contains (Fig. 1). The large oval or almost rectangular premaxilla forms a better central segment of the jaw supports the lip better and will have the lateral incisor tooth buds inclined only slightly laterally so that it is easier to work with for both the surgeon and the orthodontist. It overlaps the lateral processes slightly on both sides, so that if it is necessary to set it back, it will rest as a bridge on them and will not tend to tilt and cannot sink back behind them. The small round premaxilla may be smaller than the hiatus between the two lateral processes, so that one must try to prevent it from being forced back between and behind them thus producing a retruded upper jaw and lip. The tooth buds are arranged in a partial circle around its periphery so that the lateral incisors

From the Department of Surgery, Washington University School of Medicine, St. Louis, Missouri.

Fig. 1. Partial double cleft shown just before operation (age 5 days) and at age of 3 years. Closed by plan marked in figure 9c. Good full vermilion obtained.

Fig. 2. Partial double cleft closed in same manner as in Figure 1. Note the amount of nostril rotation necessary on both sides. These clefts may be more difficult than total ones because they have less vermilion available for the repair.

may tend to grow directly into the lateral processes or even up into the nostril floors or forward through the lip if it becomes tilted. Some of the permanent tooth buds may be entirely missing from these tiny round premaxilla.

In the newborn baby the premaxilla is nearly always anterior to the lateral processes. It may be anywhere from just in front of them to extreme positions out on the tip of the nose where it may project forward and upward like a snout. In addition to forward displacement it may be tilted from side to side or rotated. If the cleft is partially fused on one side the premaxilla may be rotated toward that side but tilted so the open edge is farther forward.

It is not uncommon to find a bend or kink in the septum just behind the premaxilla, sometimes so marked as to occlude one or both

nasal airways at birth. This may be the result of intrauterine pressure on the premaxilla.

As a rule, the premaxilla is not disturbed or set back if the lip can be closed with it in its original position unless (a) it is badly tilted or rotated or (b) it is so far forward that the elastic pressure of the closed lip might bend the septum and occlude one or both nasal airways.

If the premaxilla is to be set back, it is set back the least possible amount necessary to allow successful closure of the lip. This is done by splitting the mucosa over the bottom of the vomer and resecting a block (submucously) of the vomer just back of the premaxilla. The premaxilla is set back until it is in contact with the vomer again and immobilized by a

Fig. 3. Partial double cleft with severe initial distortion. Repair was done by a plan somewhat similar to that in Figure 9b, except that a small rectangular flap (Fig. 12) was used on one side to make the lip equal in length clear across.

Fig. 4. Total cleft on one side and partial cleft on the other. The design for repair was the same as in Figure 3 but it was necessary to rotate the nostrils a good deal more to straighten the columella and obtain the nostril symmetry shown in the final result. The premaxilla was not moved, except by the elastic pressure of the closed lip.

Fig. 5. Initial condition and repair much the same as in Figure 4 except that the patient had a very tiny prolabium which stretched out considerably during the operation and grew still more full at the age of 1 year. Notice the absence of notches or whitening defect in these patients here all of the vermillion has been procured from the lateral segment.

wire suture through both fragments or better by nailing a straight Keith needle directly backward through the center of the premaxilla and on back through the center of the vomer (Fig. 8). In setting the premaxilla back an attempt is made to correct any rotation or tilting so that it will be centered with respect to the lateral processes as well as possible. This is insured somewhat by having excised a block rather than a wedge of the vomer.

When the premaxilla is larger than the space between the two lateral processes and good firm immobilization is obtained the lip can be closed during the same operation; otherwise the closure is done about 2 weeks later.

Bony union between the premaxilla and vomer is rarely obtained either way, but the fibrous union helps a good deal in keeping it centered.

THE DISPOSITION OF THE PROLABIUM

The prolabium is the central segment of the lip and must be used in this position in the closure. The upper part of it is sometimes advanced secondarily into the columella at 3 or 4 years of age (3) but it is best not to do this primarily.

Many plans of closure have included the vermillion of the prolabium in the vermillion of the reconstructed lip but these nearly always result in a double notch. This notching is not

Fig. 6. Total double cleft lip almost no columella and lip premaxilla projecting forward from tip of nose. Premaxilla set back and lip closed early. Lip and columella elongated at $3\frac{1}{4}$ years of age by method shown in Figure 5. Upper lip maintained in front of the lower one and patient has perfect speech following closure of palate at age of 8 months.

Fig. 7. Drawings of patients showing some variations in shape, size, and position of premaxillae. These variations preclude standardization in the closure of double cleft lips to the same extent as in singles. a and f can be closed without moving the premaxillae. b requires a preliminary setback of the premaxilla. c requires a preliminary rotation and "nailing" of it in the midline. In d the premaxilla can

be loosened slightly from the premaxilla and swung into the midline without moving the bone. a triangular or rectangular flap closure being used on the total side and a ∇ excision on the partial side. e The patient shown in this illustration will probably require closure with rectangular flaps from both sides to elongate the lip as shown in Figure 12.

Fig. 8. When the premaxilla is too far forward to permit closure of the lip, it may be set back by submucous excision of a block of bone from the vomer. This removal of a block, rather than a wedge, permits the pushing of it directly back like closing a drawer rather than tilting it back. This factor is of some advantage, as the finished lip should

slant forward. In the profile view from above downward. At right the premaxilla is being set back until it rests as a bridge on the two alveolar processes. It is anchored by means of a straight steel needle which is driven through the center and on back through the bony ridge at the bottom of the vomer.

Fig. 3. Design for closure of the three most common types:
a, Total double cleft lip; b, b, Mirault flaps are turned down from either side and united beneath the prolabium; c, A flap closure is done on the total side and a V excision operation on the partial side. Partial double cleft lip is less the same general manner as in but is good deal more difficult because of the attenuation of the vermillion. See text for detail of the method.

easy to eliminate by secondary procedures as it is due to an inherent thinning and upward direction of the vermillion on both sides of the prolabium.

Consideration of the cupid's bow configuration of some normal lips has somewhat confused this issue. The occurrence of the cupid's bow varies a good deal in normal lips and in any event it is an upward prolongation of the upper edge of the vermillion beneath each philtrum. The lower edge of the normal vermillion has a gradual downward curve from the center outward without any upward notches, and it is almost impossible to get this when the thin U-shaped vermillion of the prolabium is used as the central portion of the new lip.

It is thought best to use a plan in which an incision is made at the mucocutaneous junction all the way around the prolabium and its vermillion is turned back as a flap to be used for lining if necessary.

DESIGN FOR CLOSURE

Many of the features of the modified Mirault operation for single cleft lips (1-2) are used in

Fig. 4. An incision is made in the buccal fornix on either side and undermined is carried upward almost to the orbital borders until the cheeks have been separated from the underlying facial bones. The mucosal incision is then carried forward to the nostril between the upper lateral and alar cartilages, and the skin is separated from the alar cartilages with small scissors. The latter maneuver allows the skin to slide on the cartilage and the nostril to be rolled into tube without corrugation.

Fig. 11. a) Left, Crile clamps are placed to prevent bleeding and both sides of the lip are opened up going completely through the lip with a stab blade knife and using a perpendicular sawing motion. Any skin remnants are sliced off of the vermilion flaps. The vermilion of the prolabium is cut loose from the skin and turned back all around. b) The closure is done with many fine silk sutures, put in not more than 1 to 2 millimeters from the wound edges and about as far apart. Any stay sutures are put in from the inside and are not visible. The vermilion is closed by interdigitating small flaps.

Fig. 12. Design for closure when a tiny prolabium is present. Rectangular flaps are turned down from either side and united beneath the prolabium to increase the length of the lip. In general a full short lip is preferable to a tight long one, so that this design should only be used when the prolabium is quite short from above downward.

closing the double cleft lips. Usually a flap is turned down from the inner surface of the lateral border of the cleft on each side and they are brought together in the midline beneath the prolabium (Fig. 9c). If the cleft is partial on one side and total on the other side a V excision operation may be used on the partial side and a Mirault flap on the total side (Fig. 9b). When the prolabium is unusually large and long so that the Mirault flaps

under it might result in too long a lip, 2 or 3 millimeters of skin can be excised from the bottom of the prolabium to shorten it. If the prolabium is tiny the lateral flaps may be designed in a rectangle (rather than a triangle) to elongate the lip (Fig. 12).

In marking out symmetrical clefts with the columella in the midline, a transverse line is imagined across the prolabium at the level of the base of the columella, and the points A

Fig. 3. Initial repair at the age of 1 year. The psychological handicap as very great and all probably never be entirely overcome. As a matter of fact, he called for a mirror as soon as he had awakened from the anesthetic, and kept it constantly under his pillow so that he could reassure himself several times daily that his dream had come true and that he was really going to be like other children.

are marked on either side where this line crosses the mucocutaneous junction. *A* is marked just inside the lower point of the nostril rim on each lateral side of the cleft, being careful to place it in such position that a good nostril will be formed when *1* is approximated to *A* and marking it symmetrically on the two sides (Fig. 9).

The point *C* is at the bottom of the skin of the prolabium in the midline and equidistant from the two *A* points. *B* is $\frac{1}{3}$ of the distance from *C* back to *A* on the curved lower border of the skin of the prolabium on either side.

C' is on the mucocutaneous line of the lateral part of the lip and is opposite the most medial point where there is still full thickness of the vermillion.

To locate *B'* the straight line distance *AB* is measured with small calipers. One point of the calipers is then set on *A* and the calipers rotated until the other point is *BC* distance from *C*.

Fig. 4. Initial repair at the age of 3 years. Though the palate was not cleft, patient has so much forward protrusion of the incisor teeth that it was thought best to remove them and substitute a bridge.

The above can be considered as a standard marking and can be altered when necessary. For instance, when the cleft is partial on one side the line *4 B'C'* is sometimes a straight one so that *B'* can be omitted and a straight incision made from *A* to *C'* and a *V* closure done on that side (Fig. 9).

THE CLOSURE

The above points are punctured in and the lines scratched in with 5 per cent alcoholic methylene blue using a fine mechanical drawing pen. The lines are then lightly incised with a knife with care not to cut the points out. An incision is then made in the buccal fornix on each side and carried upward to separate the lip from the upper jaw (Fig. 10). This undermining is carried upward almost to the orbital border until the cheek is separated from the underlying facial bones, and the space between them is packed temporarily with gauze soaked in 1:5,000 adrenalin solution.

The buccal fornix incision is then carried upward inside the lateral wall of the nostril to divide the mucosa between the upper and lower lateral cartilages of the nose until the nostril can be rotated into position and *A* can be brought over to *A'* without tension. A small fine scissors is introduced through the buccal fornix and the lower lateral cartilage of the nostril is separated from the skin covering by alternate spreading and dissecting up to the midline (Fig. 10).

Fig. 15. Elongation of the columella by advancing a flap from the upper lip into it. The small cut in the septum out near the tip is usually necessary to get the tip forward, and is filled in with small darts on the sides of the flap which come from the nostril floor. The defect in the lip is closed without suturing it to the new columella. (From Brown and McDowell (3) Courtesy J. B. Lippincott.)

Fig. 6. Total double cleft similar to that shown in Fig. 6. Closure as done during the first days of life. The columella elongated at about 3½ years of age, and a preserved L-shaped cartilage transplant inserted into the nose at the age of 6½ years. (The improvement shown from left to right. Many of these patients who are born without columella have a deficiency in the septal support of the nose. (Insert shows shape of the transplant.)

The lines ABC are then incised through the full thickness of the lip, a stab blade knife being used with a perpendicular sawing motion (Fig. 11). The small flap $A'B'C'$ is rotated 180 degrees into the nostril floor. The vermillion of the prolabium is turned backward as a flap to use for lining and $A-1$ and $B-B'$ are approximated on both sides. No 000 white silk sutures being used subcutaneously and No 000 black silk sutures in the skin. $C-C'$ are approximated directly under C and fine interrupted black silk skin sutures are placed all along between $A-B-C$. The vermillion closure

is done by interdigitating zigzag flaps from the two sides. The inside mucosa from the two sides is sutured to the prolabium vermillion which was turned back. The nostril floor flaps are trimmed and sutured to the portion of the prolabial skin inside the nostrils and mattress sutures are put through the nostril walls to aid in shaping them. Stay sutures may be put clear across the lip from the inside, encompassing the full thickness of the lip except the skin to avoid any visible suture marks on the outside. (The type described by Lane is a good one.)

A Logan bow is strapped to the cheeks to protect the lip and take tension off of it while crying and the nurses keep the suture lines free of crusts by frequent cleansing. The skin sutures are left in 5 days and the others a few days longer. The baby can usually be fed with a bottle after the first week if the holes in the nipple are enlarged and the child is discharged from the hospital after all sutures are out.

Any surgery on the palate is delayed until about 18 months of age to permit the tooth buds to migrate out of the palate into the alveolus.

The possibility of secondary procedures (3) on the lip is considered from the beginning with the parents, but they will be fewer in number and less in extent if the primary closure is a good one.

Those children who are born with a total double cleft and almost no columella will frequently require a secondary elongation of the latter (Fig. 15) so that this may be considered standard in this type of patient. Further elevation of the nose may be obtained when desirable by an L-shaped cartilage transplant (Fig. 16).

Maintenance of the size and structure of the upper dental arch is important in these patients for lip support as well as for other reasons. The child's dentist is contacted early so that proper dental hygiene may be instituted and he may help later in providing or securing adequate orthodontic care. Limited prosthodontia may eventually be necessary in patients with total clefts.

In addition to dental care, those children who have associated palate clefts may require the assistance of speech therapists and otolar

ingologists. Tonsillectomies and adenoidectomies should not be done routinely but they may be carried out if necessary for reasons of general health or especially if the tonsils and adenoids are contributing to any loss of hearing.

The plastic surgeon can render an additional service if he will examine these patients each year throughout the growing period and advise the parents in regard to these problems as they arise. Though starting with a severe initial

handicap these children often prove to be brighter than average and succeed so well in later life that one feels well repaid for the extra time and effort required in providing the best possible care for them.

TRANSPLANTATION OF THE URETERS INTO THE RECTOSIGMOID

YERRANT JIDIGIAN MD and WILLIAM BICKERS MD Beirut, Syria

CONGENITAL or acquired disease of the urinary bladder may render it incapable of performing its function as a reservoir for collecting the urine and emptying it periodically. The congenital type most frequently seen is extrophy of the bladder (ectopia vesicae). In this anomaly local arrest of growth occurs and the child is born with a defect in the lower anterior abdominal wall. The posterior wall of the bladder is seen as a strawberry like swelling in the suprapubic area. Examination of this strawberry like bulge reveals two small openings on either side through each of which urine is jetted at regular intervals. There is often an associated anomaly of the urethra and other genital organs. Many of the patients die in early childhood from ascending infections to the kidneys or from other congenital defects that are not compatible with life. It occurs according to Spooner 4 times in every 116 000 births according to Neudoerfer once in 50 000 births. Approximately 50 per cent of all persons so afflicted are dead by the tenth year of life.

Injury to the bladder may be the result of difficult and prolonged labor. The bladder and the vesical sphincter as well as the vagina may be lost by pressure necrosis. Such patients are frequently admitted to the hospital with a history of a long and difficult labor terminating in instrumental delivery or spontaneous delivery of a macerated fetus. When the tissue loss is great plastic repair is impossible and ureterosigmoidal transplant is the only operation that will restore continence. In other cases, the damage to the bladder is the result of accidents or bullet wounds, resulting in complete or almost complete destruction of the bladder and sphincter. In most of these cases where tissue loss is great improvement cannot be secured by plastic operations.

From the Departments of Surgery and of Gynecology and Obstetrics, American University of Beirut, Beirut, Syria.

Very early the idea was suggested of establishing continence in these patients by surgically producing a cloacal condition such as exists in birds. According to Mayo the first attempt at such an operation was made by Simon in 1851. In 1896 Maydl transplanted an inverted portion of the bladder wall with the ureters attached into the sigmoid. Moynihan in 1906 performed an extraperitoneal operation in which he inverted the large part of the bladder into the anterior wall of the rectum. To Coffey must go the credit for laying down the principles which have given an anatomico-physiologic clarification of the surgical problems involved. He attracted attention to the fact that when a duct opens into a cavity to discharge its contents, it runs in its terminal part through the wall of the viscera and then opens into its lumen. The terminal part of the duct is intramural in relation to the cavity into which it opens. This is illustrated by the salivary ducts opening into the mouth, the common bile duct opening into the second part of the duodenum, and the ureters opening into the bladder. This anatomical relationship provides a sphincter mechanism and prevents regurgitation of urine into the ureters. Coffey therefore transplanted the ureters into the rectosigmoid by burying the terminal parts into the wall of the sigmoid and the very end of the cut ureter into the lumen of the sigmoid. In 1926 Mayo reported 66 cases of operations carried out by the Coffey technique in which 48 patients were said to have obtained satisfactory results. These operations were done in two stages. In most of his cases a ureteral catheter was used and kept *in situ* for a few days after the operation to prevent obstruction of the ureters. These catheters had one end inside the ureter and the other was brought out of the anal opening. The operation however was improved by Mr Henry Wade of Edinburgh who used a modified Coffey Mayo technique. Mr Wade transplanted both of the

Fig. 1. Incisions are made through the posterior parietal peritoneum exposing the ureters. Ureters divided at the ureterovesical junction and a rubber band tied proximal to the cut end preventing spill. Clamp is passed behind the left mesosigmoid and the left ureter is brought through the mesosigmoid before implantation.

Fig. 2. After the left ureter has been drawn through the mesosigmoid it is now possible to perform the implantation without kinking.

ureters into the rectosigmoid at one operation and he did not make use of the ureteral catheters. Instead he left a wick of catgut inside the ureter to prevent its closure.

At the American University Hospital we have during the last 6 years transplanted the ureters in 19 patients. We have used Mr Wade's technique with changes which are believed to offer certain advantages.

TECHNIQUE OF OPERATION

Thirty-six hours before the operation the patient is given a purge of castor oil. Following this she is put on a fluid diet consisting of water, tea, and lemonade. If her fluid intake is not sufficient she is given fluids in the form of infusions or hypodermoclyses of 5 per cent glucose in saline. The morning of the operation she is given enemas until the return is clear. An injection of morphine and atropine is given 45 minutes before the operation. Ether inhalation anesthesia is used. When fully anesthetized the patient is put in Trendelenburg's position.

A midline infraumbilical incision is used. The right ureter is first identified as near the bladder as possible and the peritoneum over the ureter is incised. The ureter is dissected free for a distance of about 15 centimeters care being taken to leave the periureteral and the ureteral vessels attached to the ureter. A ligature is placed on the ureter as near to the bladder as possible. The ureter is then cut above the ligature with a scalpel (the crushing effect of scissors is avoided) isolated for the

Fig. 3. Longitudinal incision, 1 centimeter long divides the cut end of the ureter and the flaps everted with a suture of No. 0 plain catgut.

Fig. 4. a, Incision down the muscularis b, broad N suture through peritoneal flap, perireteral tissue and out through the opposite flap c, additional supporting sutures similarly placed d, mucosa of bowel opened with hot cautery and sutures tightened which brings the everted end of the ureter to the bowel lumen, e, sutures tied, anchoring the ureter and approximating the peritoneal covering of the bowel.

appropriate length with the perireteral tissues and lifted into the abdomen. A rubber band is placed around the ureter 2 centimeters proximal to the cut end to prevent spill and to prevent bleeding from the divided ureteral vessels. The divided peritoneum is sutured.

The left ureter is similarly exposed. On the left side however an artery clamp is passed along and parallel to the ureter behind the pelvic colon to the root of the mesentery where the clamp is forced through the mesentery of the sigmoid. The end of the divided ureter is caught by the point of the clamp and pulled

Fig. 5. N chromic sutures are passed through the fascia of the left psoas muscle and the appendices epiploicae and upon being the sigmoid is rotated so that the points of implantation are immobilized in the retroperitoneal space.

up so that it is above the pelvic colon (Fig. 1). The left ureter is now anterior (Fig. 2).

Two longitudinal slits are made in the cut ends of the ureters (Fig. 2) and the flaps turned upward like cuffs and held in place by a stitch of plain catgut (Fig. 3).

The pelvic colon is chosen for the site of the implantation, the left ureter being implanted high and the right lower down. It is best to use the tenia of the colon for the site of implantation. This is incised obliquely for a distance of $\frac{3}{4}$ inch and flaps of serosa muscularis are turned out without opening the bowel mucosa. The distal portion of ureter is laid in this bed, and the peritoneal flaps sutured over the buried portion of the ureter. The terminus of the ureter with the turned up cuffs is left protruding (Fig. 4). After suturing of the flaps, which must be neither too tight nor too loose the mucosa is opened by cautery and the end of the ureter pushed into the lumen of the colon. One additional suture closes the peritoneal flaps over the buried ureter.

The ureter must not be denuded of the perireteral tissue. For fixing the ureters the sutures must pass through the peritoneal flaps and the outer layer of the ureter and periure-

teral tissue, but not through the lumen of the ureter

It is important that the ureters not be pulled upon by the weight of the colon into which they are implanted. Therefore the segment of colon into which the implantation is made is fixed to the posterior abdominal wall at the sites of the exit of the ureters from the posterior parietal peritoneum. This fixing (sigmoidopexy) is best done by making use of the appendices epiploicae. By this same sigmoidopexy the sites of the implantations become extraperitoneal. This is thought to be one of the most important steps in the operation (Fig 5).

The abdominal wall is closed without drainage. Following the operation a rectal tube is introduced into the rectum and kept there. The patient is given about 3 liters of 5 per cent glucose in saline intravenously each day. This increases the urinary output and puts pressure into the renal pelvis and ureters and thus diminishes the risk of obstruction to the urinary outflow.

During the first few days after operation these patients develop an acute irritation of the rectum, but this passes away after 2 weeks. Their fluid intake and urinary output must be measured daily. For the first 3 or 4 weeks the patient passes urine every 3 or 4 hours during the day and once every 5 or 6 hours during the night. It is interesting to note that after several months the feces and the urine do not mix and the patient knows when she is going to pass urine and when she is going to have a bowel movement.

One of the patients with tuberculous cystitis had a double ureter on the left side and a single ureter on the right side. The 3 ureters were transplanted at one operation. The 2 ureters on the left side were transplanted into the same opening, the 2 ureters being approximated by sutures of plain catgut going through the perireteral tissues only.

PROGNOSIS

Sixty-six patients who were subjected to this operation were reported from Mayo Clinic in 1926. Forty-eight of these were living and 18 were dead at time of report. Twenty nine of the living patients reported upon their condi-

tion and of this number 25 were satisfied with the results, 2 had poor control of urine by rectum, 1 was incontinent and 1 complained of chronic irritation of rectum with diarrhea. In the Mayo series the deaths were classified in two groups, those patients dying in the hospital and those dying after leaving the clinic. Of the former, 5 succumbed to peritonitis and 6 to pyelitis, pyelonephritis and pyelonephrosis. Seven patients died after leaving the clinic, all from some disease not related to urinary tract.

Transplantation of ureters into the rectosigmoid has been done 19 times at the American University Hospital since 1937. The technique which has been described was used in all cases. The indications for operation were as follows: (1) exstrophy of the bladder, 7 cases; (2) vesicovaginal fistula, 6 cases; (3) tuberculosis of the bladder, 3 cases; (4) trauma to perineum and bladder, 3 cases.

The surgical mortality in this series was 13 per cent. The 2 deaths are reported in some detail below. The other 15 patients have been discharged from the hospital completely continent. The time elapsing between operation and present report varies from 9 years to 1 year. Only 1 patient in this group has been readmitted to the hospital for a urinary complaint. This was a patient with exstrophy of bladder operated upon in 1942 who was admitted 6 months after operation with acute pyelitis. This responded promptly to sulfathiazole therapy and patient left hospital within a few days. One patient complained of persistent diarrhea for several months after leaving hospital. This has subsequently disappeared. Without exception these patients began to gain weight and their general health improved soon after operation. The average patient must discharge the urine from the rectum about every 5 hours during the night and every 3 or 4 hours during the day.

DEATHS FROM TRANSPLANTATION OF URETERS

CASE 35325. In a male baby 25 days old the diagnosis was exstrophy of the bladder. On April 22, 1942 transplantation of both ureters was done at one operation. The baby died 30 hours after operation the cause anuria.

CASE 38842. In a woman 35 years old the diagnosis was tuberculous cystitis. Patient had 13 preg-

nancies of which 4 were abortions, 9 normal deliveries. Five of the children died in childhood, 4 are living and healthy. She had cystitis of $3\frac{1}{2}$ years' duration, and had been treated conservatively with irrigations and urinary antiseptics. She had never improved and for the last 2 years had had constant dribbling of urine day and night with burning. Her bladder capacity was 5 cubic centimeters. guinea pig inoculation was positive for Koch's bacillus. Transplantation of both ureters was done on May 29, 1944. Ten days later the wound opened completely and the intestines were eviscerated. These were put back and the wound sutured. The patient developed peritonitis and died 18 days after transplantation of ureters, 8 days after evisceration. There was an average of 1,000 cubic centimeters of urine daily from the rectum.

SUMMARY AND CONCLUSIONS

A simplified technique for ureterosigmoidal transplantation has been described. The im-

portant innovations are (1) elimination of ureteral catheters (2) single stage operation (3) transplantation of the left ureter only after bringing it through the mesosigmoid, thus eliminating kinking (4) eversion of the ureteral ends in order to prevent stricture (5) fixation of sigmoid to the posterior parietal peritoneum in such a manner as to extraperitonealize the sites of anastomosis.

THE OBJECT, THE VALUE, AND THE TECHNIQUE OF PREOPERATIVE AND POSTOPERATIVE X-RAY TREATMENT IN CARCINOMA OF THE BREAST

GEORGE E. PFAHLER, M.D., Sc.D. LL.D., and GEORGE P. KEEFER, M.D. Sc.D.,
Philadelphia, Pennsylvania

IN the United States cancer of the breast caused 16,379 deaths during the year 1944 or a crude death rate from this disease of 12.4 per 100,000. Since the average length of life before death is from $3\frac{1}{2}$ to 4 years, and since about 20 per cent of all cases are cured, we have a right to assume that there are in the United States at present about 60,000 cases of cancer of the breast. In a previous study we have found suggestive evidence that roentgen therapy is of value in the prevention of cancer of the breast, by treating the chronic mastitis which often precedes, and which is commonly associated with, cancer of the breast.

In this paper we shall try to present the value of preoperative and postoperative roentgen therapy. We shall omit discussion of the value of irradiation as a *primary* and single form of treatment of recurrences, the value of which is recognized by nearly everyone. We are further confining this discussion to the stage 2 with axillary metastasis, proved by operation. Harrington Greenough and Taylor, Lund, and Roeden have shown that microscopic examination is essential for accurate diagnosis of cancer in the axilla.

Roeden discusses the prognostic importance of "sinous catarrh" in the axillary glands, and says "If the sinous catarrh is of any significance, it must be conceived as an expression of a preliminary stage to the metastasis resulting from a toxic irritation, or possibly from an irritation caused by solitary tumor cells."

It would seem to us that with this thought there is an indication for preoperative irradiation whenever there are palpable lymph nodes and perhaps when there are no palpable nodes since there is a possible error of about 30 per cent in such cases. Roeden found that 36 per

cent of his 44 patients with sinous catarrh died of cancer, while only 20 per cent of 70 patients who were without sinous catarrh died of cancer.

We believe that patients with operable cancer of the breast should be operated upon and as promptly as possible. On the other hand when a patient absolutely refuses operation and refuses to see a surgeon or for some reason cannot be operated upon we should give the patient with technically operable cancer the second best chance with primary irradiation. Sometimes after this preliminary irradiation, one can still induce the patient to accept operation, otherwise one must administer the radiation to the limit of the normal tissue toleration.

In using the term 'preoperative irradiation' we definitely plan for operation when possible, within 3 or 4 weeks from the beginning of the roentgen therapy, and as soon after the preoperative irradiation as conditions will permit. We do not refer to preoperative roentgen therapy as *just any kind of x ray therapy* that is given before an operation but we refer to the treatment given preparatory to and with operation definitely planned. We advise consultation with the family physician, the surgeon and the radiologist at the beginning whenever cancer of the breast is suspected, so that the plan of management may be outlined and controlled.

The "operability" of cancer of the breast should not depend merely upon the consent of the patient. Portmann as a radiologist and Haagensen as a surgeon have repeatedly demonstrated that many patients with advanced cancer of the breast would be expected to live longer and be more comfortable without operation. Portmann very properly says, "All patients with cancer of the breast may be oper-

ated upon, and therefore would be operable. Therefore these terms operable and inoperable should be discarded and *surgically curable* and *surgically incurable* should be substituted which would define the objective and limitation of surgical procedures.

The conditions of "operability" (surgically curable) and "inoperability" (surgically incurable) as described by Portmann agree practically with those given by Haagensen (surgeon) and Stout (pathologist). After reviewing the results which they have obtained, Haagensen and Stout say

"From these correlations we have drawn up a rule for judgment of operability in breast carcinomas as follows: Women of all age groups, who are in good enough general condition to run the risk of major surgery should be treated by radical mastectomy except as follows:

"1. When the carcinoma is one which developed during pregnancy or lactation.

"2. When extensive edema of the skin over the breast is present.

"3. When satellite nodules are present in the skin over the breast.

"4. When intercostal or perasternal tumor nodules are present.

"5. When there is edema of the arm.

"6. When proved supraclavicular metastases are present.

"7. When the carcinoma is the inflammatory type.

"8. When distant metastases are demonstrated.

"9. When any two or more of the following signs of locally advanced carcinoma are present:

(a) ulceration of the skin (b) edema of the skin of limited extent (less than one-third of the skin over the breast involved) (c) fixation of the tumor to the chest wall (d) axillary lymph nodes measuring 3.5 centimeters, or more in transverse diameter and proved to contain metastases by biopsy (e) fixation of axillary lymph nodes to the skin or the deep structures of the axilla, and proved to contain metastases by biopsy

They say further

"If these criteria had actually been followed in judging operability in the series of 650 radical mastectomies which we have reported a total of 100 of the patients would not have been operated upon. Yet the number of patients permanently cured would not have been decreased by a single one.

Harrington who has reported on 6,558 cases of cancer of the breast from the Mayo Clinic does not exclude the pregnant lactating breast or those with a few skin nodules near the tumor

PREOPERATIVE IRRADIATION

An insufficient number of cases of preoperative irradiation have been recorded to justify any final conclusions from statistics. Many authors have the impression that it is of definite value. Hoffmeyer (Copenhagen) found that after 1000 to 4,800 r were used, histologically a diminution of the cancer cell area corresponds approximately to the macroscopic recession of the tumor but in no case was there complete disappearance of cancer cells. With the technique which we use, it is not our aim or expectation to destroy all cancer cells but only the more malignant cells which are the more sensitive, and which are more likely to give rise to metastases. Peters of the Toronto General Hospital says, "Stage 2 would be markedly improved by the institution of preoperative radiation in preference to and in some instances combined with postoperative treatment.

THEORETICAL AND BIOLOGICAL EVIDENCE FAVORING PREOPERATIVE IRRADIATION

Tendency of preoperative irradiation to demoralize or destroy the more malignant types of cells
It is well known that the microscopic grade of malignancy has much to do with the prognosis of carcinoma of the breast after operation. As indicated in statistics prepared by Harrington in 1935 at the Mayo Clinic, approximately 91 per cent of the group of 1,907 patients having invasion of the lymph nodes had cancer of microscopic grades 3 or 4 and of the 481 patients having these grades 3 and 4 who were traced, only 20.5 per cent who had operation alone lived 5 years. Harrington found in a study of 2,396 operable cases at the Mayo Clinic, 80.6 per cent were in stage 2. It will be further observed from his table that the patients with cancer of microscopic grades 3 and 4 represented 90 per cent of the 1,907 patients with involvement of the lymph nodes and those with grades 1 and 2 approximately 10 per cent. It must be clear therefore that the greatest problem arises when dealing with the microscopically more malignant grades 3 and 4, with axillary involvement or in the clinical stage 2. This type represents approximately 80 per cent of all operable cancer of the breast. These microscopic grades of malignancy can be deter-

mined only after a complete operation and a study of the entire breast (Dawson and Tod). Even grades 1 and 2 (representing 10 per cent of all cases) are liable to contain some of the more malignant cells. Therefore, when axillary involvement or enlarged lymph nodes are present, all patients should have both preoperative and postoperative irradiation. Dawson in a study of 460 mammary cancers of all stages of growth found the axillary tissue involved in 70 per cent. Lynham estimated that 75 to 95 per cent of all mammary cancers show spread beyond the actual breast when first examined.

It happens that, so far as the microscopic classification is concerned grades 3 and 4 are especially radiosensitive while grades 1 and 2 are much less so. This too, is a matter of common knowledge and common agreement. Unfortunately grades 3 and 4 lead to early and extensive metastasis and therefore give most of our failures. This is evident in the table mentioned which shows that in 91 per cent of the total cases of involvement of the lymph nodes the cancer was of grades 3 or 4. It is also self-evident that unless the irradiation is applied to the area in which the malignant cells are located ultimate failure will result. Therefore the earlier the diagnosis is made before distant metastasis occurs and the earlier the patient is treated by irradiation the better will be the end result. Bloodgood recommended immediate irradiation of the axilla and the breast in all cases of doubtful or malignant tumor.

Because the more malignant type of cells (stages 3 and 4) are rendered less malignant by even a moderate amount of irradiation it is fair to assume that such irradiation given to a patient with carcinoma of the breast will partially devitalize the more malignant type of cells which are the cause of extensions and of the surgeon's failures (Halley and Melnick). Because of devitalization of the cancer cells preoperative irradiation should decrease the recurrences which are due to implantation during operation (Brandes 1946) and should also render less liable distant metastases which are caused by emboli that have been carried through either the lymph stream or the blood stream such as may result from the manipula-

tions connected with the operative procedures. Such devitalizing effect of irradiation on the more malignant cancer cells surely occurs immediately, even though it cannot be demonstrated at once microscopically. Therefore there is no advantage from this standpoint in prolonging the interval before operation and the operation can take place as soon as the proper amount of irradiation has been given to the tumor areas which we estimate to be about 1200 roentgens given within a period of 2 weeks.

Normal tissues less receptive to implantation after preoperative irradiation. Biologic experiments (Murphy) and (Russ and Scott) indicate that in addition to the effect of irradiation on the malignant cells there is an effect on normal tissue which is detrimental to implantation of carcinoma. Russ and Scott utilized rats and have exposed to irradiation two of the opposing quadrants of the outer two-thirds of a circle of skin protecting the central area of the circle and the other two quadrants. They then implanted malignant disease in the unexposed center. In all instances the tumor tissue grew by preference into the unirradiated areas. This effect was evident even when as little as 50 or as much as 100 per cent of an erythema dose was used and was also effectual even when the irradiation was given several days before the inoculation.

In view of these facts preoperative irradiation is definitely indicated especially when carcinoma of the breast is in clinical stage 2. The preoperative treatment which we recommend can usually be given in approximately 2 weeks and the patient can be operated on usually during the third week. There is therefore no great delay in the operation and such irradiation will not interfere with the technical procedures of the operation itself. Preoperative treatment has been recommended by one of us (Pfahler) since 1915 but until recent years relatively few patients have been referred for such treatment, and not enough patients have been given the short type of preoperative treatment to make of value any statistical statement regarding them.

In the past, preoperative treatment has been given to three types of patients (1) those with cancer in clinical stage 2 previously described

(2) those with cancer belonging to Steintal group II-C, which is doubtfully operable but which is made more operable by preoperative treatment and (3) those with cancer which is totally inoperable but which by prolonged treatment and an interval of 2 or more months is sometimes made operable. For the sake of brevity we will confine this discussion to cancer which has invaded the axillary nodes but which is still clearly operable, and which we classify as stage 2.

Time for operation after preoperative irradiation As indicated by the investigations of Halley and Melnick one must not wait too long or regrowth of surviving tumor cells will occur within 4 to 6 weeks. We are recommending operation in about 3 weeks after beginning irradiation or a few days to a week after finishing the preoperative irradiation or as soon as circumstances permit.

It has been our experience that usually the more advanced cases are referred for preoperative or postoperative x ray treatment and the more favorable cases in stage 2 are not referred. Adair has studied the results of 7,419 cases of breast cancer of which 47.6 per cent or 3,535 cases were operable. He states, "The 194 cases treated by surgery alone—represents a 'selected group' as evidenced by the high percentage of 5 year salvage, namely 43 per cent, and the older age level. When no axillary nodes were involved 74.2 per cent 5 year salvage was obtained."

Adair did a masterful piece of research on preoperative irradiation and thought he had solved the problem. He concluded that preoperative irradiation gave no advantage, but waited from 6 weeks to 3 months after the irradiation for the operation. In 1936 Adair stated that this interval varied from 12 days to 300 days with an average of 66 days. In 1936 referring to the results of radical operation in the hands of the best surgeons, Adair said "If both the breast and axilla are involved the 5 year cures are approximately 20 per cent. Adair (1943) found Of the 337 patients having axillary involvement operation and preoperative x ray treatment 119 or 35 per cent had a five year survival while the 177 patients having axillary involvement subjected to operation immediately and

followed by postoperative x ray treatment, 74.41.8 per cent—survived 5 years.

In waiting so long after the preoperative x ray treatment Adair was undoubtedly influenced by the opinion of our late great tumor pathologist, Dr James Ewing. Dr Ewing had found that more and more cell degeneration developed as time went on but we think this delay permitted the more resistant types of cancer cell to recover as demonstrated by Halley and Melnick. The delayed operation did permit a better estimate of the value of the primary treatment of cancer of the breast by irradiation. On the other hand it had the disadvantages of delay in operation which permits growth of the radioresistant cells and extension beyond the operative or irradiated field.

Halley and Melnick have made an extensive histological study of the effects of irradiation in 300 transplantable rat tumors and also human breasts, and conclude that irradiation by fractional methods acts directly on human breast tumor cells in a two-fold manner producing early a simple radionecrosis of sensitive cells and later accumulation of mutation like effects through succeeding generation of daughter cells. Regrowth of surviving tumor cells appears 4 to 6 weeks after termination of therapy. They therefore, recommend operation within 2 to 4 weeks after a short period of preoperative irradiation.

Stewart believes that preoperative irradiation is bound to raise the number of cures more than is any other method especially in those cases in which the axillary lymph nodes are involved.

Peterson, Todd, and Russell have reviewed 601 cases treated during 1924 to 1936 some of which received preoperative treatment. They believe from observation in these cases and from results published by others that preoperative is preferable to postoperative roentgen treatment. They state, "It is now fairly generally accepted that a course of postoperative irradiation is a useful prophylactic against local recurrences."

Roeden found that the preoperative treatment yields better results than the postoperative roentgen treatment. He found in stage 1 71 per cent (38 cases) 5 year survival with op-

eration and postoperative roentgen therapy and 90 per cent of 48 patients receiving preoperative irradiation, operation, and postoperative roentgen therapy. In stage 2 operation gave only 25.5 per cent of 51 cases operation plus postoperative roentgen therapy gave 25.5 per cent ("only the more advanced cases received postoperative treatment") and with preoperative roentgen therapy, operation and postoperative roentgen therapy there was 36.5 per cent survival. He says, "Practically all cases have been given preoperative irradiation since 1928."

Time for postoperative irradiation. A review of our own records as well as a study of the literature shows that many patients are sent for "postoperative treatment at a time when they actually have evidence of recurrent disease and should not be class with "postoperative irradiation," but should be grouped with "recurrent carcinoma." It is our opinion that to get the best value from postoperative treatment the patient should be referred as soon after the operation as her general condition and circumstances will permit which is usually within 10 days to 2 weeks, even though the wound is not entirely healed. We have not found that postoperative irradiation interferes with the healing of the wound, nor have we found that the wound breaks down because of postoperative irradiation. If preoperative irradiation has been given one may wait 3 or 4 weeks after the operation before giving the postoperative treatment.

Ovarian sterilization as a preoperative or a postoperative prophylactic measure. It is well known that cancer of the breast is more malignant in young women (Sistrunk and MacCarty). Dresser found that of forty-eight women under 40 treated by radical mastectomy, only 12.5 per cent were free from disease at the end of 3 years. Lee says, Of the patients 40 years or under 27 per cent were alive and well at the end of 5 years, whereas of those over 40 years of age 45 per cent were alive and well at the end of 5 years.

Cancer of the breast also grows more rapidly during pregnancy (Steel). Haagensen gives pregnancy as a contraindication for operation. Therefore, pregnancy should be avoided in a case of cancer of the breast by arresting the

ovarian function. Experimental evidence indicates that the ovarian hormones stimulate the production of cancer of the breast in animals of a cancer strain or which have any susceptibility to the development of cancer (Loeb, Lacassagne). In cases of recurrence of metastasis, oophorectomy (Schinzinger, Beatson, Lett, Boyd, Torek, Thomson, and Fouveau de Courmelles) and also ovarian sterilization by irradiation (Dresser, Hoffman) have been followed in a considerable number of cases by a disappearance of the lesions. A woman who has had carcinoma of the breast is proved to be susceptible to the disease and Harrington's (January 1946) statistics indicate that approximately 70 per cent of 3,511 traced patients with axillary metastases have remnants of the disease in the system after operation or they would not have died of the disease within 5 years. Consequently, any stimulation from the ovaries in such cases is liable to shorten life. Therefore, we recommend ovarian sterilization for all women with cancer of the breast who are still in the menstrual time of life. Reports by Torek and statistics by Ahlborn seem to indicate some value of ovarian treatment even after the menopause. Dresser on the other hand has not been able to recognize any benefit after the menopause.

TECHNIQUE

The technique has varied tremendously not only among different radiologists but even in our own experience. This is natural for radiotherapy has been a rapidly developing procedure. New knowledge has accumulated since the discovery of roentgen rays approximately 50 years ago concerning both the disease and the effects of irradiation. Therapeutic technique with these rays has been developed or undergone evolution particularly during the past 38 years, beginning with a few scattered workers and gradually spreading until now it is not only universally utilized but is being used in all branches of medicine. Our own experience (Pfahler) in treating carcinoma of the breast covers over 44 years and naturally there has been a considerable variation in technique during this evolution. No technique can be standardized even yet. Considering general principles our own technique has in

volved from the beginning to the present time the use of fractional dosage carried over a considerable period. Therefore, instead of reviewing all that has been done and the variations that have taken place, we will be content with a description of our own present technique, which may be modified as newer knowledge is developed.

Technique for short preoperative treatment

Short preoperative treatment is used when the cancer is still clearly in an operable stage but is no longer confined to the breast. The object is to devitalize the more malignant type of cells with moderate dosage without causing undue delay or interference with the operation itself and with no expectation of destroying all cancer cells in the treated area. Of course no effect is produced on the cancer outside of the area treated. Ordinarily we aim to finish this preoperative treatment in approximately 2 weeks and to give approximately 1000 to 1400 roentgens through each side of the breast and through the axillary and supraclavicular region and when there is much fat or advanced axillary glandular enlargement an additional posterior axillary portal is used. This is approximately the same dosage in each portal as is used in the preoperative treatment in Stockholm—Radiumhemmet and Maria Hospital (Berven and Roeden)—Sophiahemmet (Forsell)—Red Cross Hospital (Åkerlund) but we use four or five portals instead of two because we believe that it gives better distribution even though it involves more work. The cross-fire value of this will equal approximately 200 to 350 r units in the diseased area at each treatment or a total of 1000 to 1400 roentgens in the tumor area. For all of this treatment, we utilize 180 or 200 kilovolts, 50 cubic centimeter distance, and 0.5 millimeter of copper filtration. For portals (Fig. 1) we utilize the space from the parasternal line to the nipple line, turning the patient on the side and irradiating tangentially so that the rays will include the chest wall but not penetrate the lungs. A similar tangential dose is given through the mammary area externally extending from the midaxillary line to the nipple line also tangentially avoiding penetration of the lung but including the chest wall. An axillary portal occupies the space between the posterior and

the anterior axillary folds, and the rays are directed upward and inward so as to irradiate the axilla, the coracoid or infraclavicular region and the deeper portion of the supraclavicular area. Tangential rays are again utilized and the chest walls and the upper mediastinum included but not the lung. A portal is then utilized including the supraclavicular region and the coracoid region and the rays carried from the lower border of the anterior axillary fold upward and inward to the lower border of the sternoclavicular junction. In stouter persons, a similar portal is utilized through the posterior axillary field the same general principles being carried out. This should give a rather even distribution of irradiation and should give approximately an erythema dose value into all of these tissues. This amount of irradiation is intended to be supplemented by postoperative irradiation. We are very particular about the exact division of portals, and the exact direction and the distribution of the rays so as to secure a uniform irradiation and to miss none of the corners.

Technique of postoperative irradiation (Fig. 2)

We generally begin postoperative treatment through a portal occupying the supraclavicular and coracoid region outlined approximately similar to the one utilized in the preoperative treatment and for a second portal of entry we usually use the posterior axilla, with the arm thrown over to the opposite shoulder and the rays directed into the axilla, into the deeper part of the supraclavicular region and toward the upper part of the mediastinum. Generally the arm cannot be abducted sufficiently to get a portal of entry into the axilla itself after operation. As a third portal we utilize a large area extending from the lower border of the coracoid and supraclavicular portal to the level of the epigastrium and extending from the right border of the sternum to the left anterior axillary fold. Because of the large area involved, because of the lung and the heart underneath and because irradiation of this area is apt to give rise to radiation sickness, we give relatively smaller doses over this field. We utilize for postoperative treatment over this portal the so called low voltage technique, using 135 kilovolts, 2

Fig. 1. Shows the areas utilized for preoperative treatment. These areas are carefully marked on the skin so that no part of the skin is doubly treated or is missed. The supraclavicular area is directed to the lymphatic area extending from the axilla to the upper mediastinum. In order to bring the axillary tissue into the field, a small sandbag placed in the posterior axillary depression and with the arm separated from the body will permit more radiation to reach the deeper part of the axilla. For the inner field of the breast, the patient is rotated on the affected side with the sandbag placed under the breast so as to bring the breast almost on a level with the treatment localizer. For the external portal, the patient is rotated to the opposite side. The breast is propped up with a sandbag so as to bring not only the entire breast but part of the tissue outside of the breast into the field for treatment. For the axillary field, the arm is placed above the head and the rays are directed into the axilla and toward the base of the neck and upper mediastinum.

millimeters of aluminum filtration and 50 centimeter distance. Generally we can give only about 200 or 300 roentgens in each application sometimes less but we aim to deliver into this area a total of approximately 1 800 to 2,400 roentgens counting both preopera-

tive and postoperative treatment. The treatment is given according to the saturation technique, and we should not exceed a full erythema dose at any time. We aim to deliver into the axilla coracoid and supraclavicular region approximately 1 800 to 2,400 roentgens

Fig. 2. For postoperative irradiation the supraclavicular area is handled as in Figure 1. The operative field is brought into position by rotating the patient so as to level the area as much as possible. The axillary space is treated postoperatively chiefly through the posterior axilla because one generally cannot raise the arm sufficiently to go directly

This will bring about a definite erythema, but we have not found that it interferes with the healing of the wound or the convalescence of the patient. If there has been no preoperative irradiation we believe that the postoperative treatment should begin about 2 weeks after operation while the congestion is present and while any cells that have been implanted or transferred are not yet completely adapted to the tissues of the host and while the cancer cell is more radiosensitive than it would be later. If preoperative treatment has been given we can wait 3 or 4 weeks to begin postoperative treatment.

To help in the avoidance of radiation sickness we generally give intramuscular injections of 10 milligrams of thiamin chloride or more recently one of two preparations with the following formulae, in each cubic centimeter of solution

	milligrams		milligrams
(a) Thiamin hydrochloride	0	(b) Thiamin chloride	30.0
Riboflavin	1	Riboflavin	3.0
Pyridoxine hydrochloride	1	Nicotinamide	70.0
Calcium pentothamate	50	Calcium pentothamate	5.0
Nicotinamide	50	Pyridoxine	5.0

THEORETICAL AND BIOLOGIC CONSIDERATIONS FOR POSTOPERATIVE IRRADIATION

Local postoperative treatment is intended (1) to destroy any malignant cells that may have been transplanted during operation (2) to destroy any microscopic remnant of cancer tissue which the surgeon may have missed and (3) to render the normal tissue more resistant to cancerous growth. Definite evidence of implantation is furnished by the rare observation of clearly demonstrable stitch hole recurrences. Other more frequent implantations probably occur under the skin flap. It is our impression that remnants of cancerous tissue left behind are rendered more malignant and also more radiosensitive by the congestion following the traumatism of operation unless controlled by postoperative irradiation. It is generally admitted that local and regional recurrence is the result of incomplete operation but since 38 per cent of the patients whose operation is a failure have local recurrences and 15 per cent axillary recurrence

(Creyssel and Morel) it is seen that 53 per cent of the operations which fail are incomplete. All of these recommendations are intended to lessen the number of failures connected with surgical intervention for in the clinics where the basic principles of radiotherapy have been followed most closely and where the radiologists have mastered a good technique, postoperative irradiation has become almost a routine procedure.

Since almost everyone recognizes that roentgen therapy is of value in the treatment of recurrent cancer and since recurrent cancer is proof that cancer cells were left behind at the time of operation it is reasonable to assume that the same irradiation given while the disease is only microscopic and the cancer cells not yet well nourished and adapted to their surroundings, will produce even a better chance of destroying the disease. It is unreasonable to expect cure or prevention of cancer that develops at points distant to the area treated.

Haagensen and Stout in their masterful review of 640 cases in all stages obtained 47 per cent of 5 year survivals after operation but local recurrences occurred in 22.8 per cent. It would seem that thorough postoperative roentgen treatment might prevent many of these since even they favor irradiation for recurrences. Surely recurrences at the beginning are more easily controlled.

Tables I, II, III IV and V represent a fair review of the available records in most of the leading clinics throughout the world so far as they can be recognized as to the stage of the disease.

DISCUSSION

Every physician surgeon or radiologist knows that carcinoma of the breast and its treatment is a very complicated problem. As will be observed in Table I with surgery alone referring to stage 2 cases, the 5 year survival percentage varies from 24.3 to 47.3 per cent, and with surgery and postoperative roentgen treatment, the variation is 25.5 to 41.8 per cent. In general, the results show some improvement as a result of postoperative irradiation.

In Table II there is involved a much larger percentage of cases which were treated by surgery alone in different clinics as compared with

the combination of surgery and postoperative irradiation in another series of clinics. It has not been possible in all instances to separate in the records the cases in stage 2, and because of that fact some excellent records have been omitted. It is self-evident that if the records are made up of stages 1 and 2 or possibly stages 1, 2, and 3, the end results will vary with the number of stage 1 cases that are added. It will be seen however that in spite of these tremendous variations there is a general improvement when postoperative irradiation has been used.

In the group of stage 2 cases in Table III treated with preoperative and postoperative roentgen therapy, the general results are shown to be still better than with postoperative treatment alone.

Table IV and the associated letter and comments refer to the records made by Dr. Gordon Richards which he is preparing for presentation in London in the near future.

Table V refers to the review of our own records of postoperative roentgen treatment during the period 1902 to 1941 or approximately 40 years. These results are influenced by the

TABLE I—RECENT COMPARATIVE 5 YEAR RESULTS IN BREAST CANCER STAGE 2

	No. cases	Percent living 5 years	No. cases	Per cent living 5 years
Adair	85	47.5	177 ¹	41.8
Graves	46	23.0	35	40
Haagensen & Stout	144	24.7	145 ²	5.5
Harrington (1940)	73	24.5	90 ³	20.4
Rorden	21	14.5	21	5.5

¹Adair says these cases were "selected."

²Harrington (Report 1940). The surgery was done in the 16 or 17 Clinics—one of the greatest clinics in the world, but the postoperative irradiation in most cases was carried out at scattered points throughout the country.

³Only the more advanced cases received postoperative treatment in the early records.

Remarks: It is the general opinion of many leading radiologists that in many clinics only the more advanced or unfavorable cases in "stage 2" are referred for postoperative irradiation. Haagensen and Stout say in evaluating these data we again meet with the fact that postoperative prophylactic radiation is more often administered to advanced cases which produces the results.

operative results from many different surgeons and therefore again can be depended upon only as an impression.

The statistical records show a tremendous variation in the terminal results whether pa-

TABLE II.—RECENT COMPARATIVE 5 YEAR RESULTS IN BREAST CANCER IN STAGE 2—OPERATED UPON IN DIFFERENT CLINICS SHOWING RESULTS WITH SURGERY ALONE AND WITH POSTOPERATIVE IRRADIATION

Surgery alone			Surgery and postoperative irradiation		
Author	Total No. cases all stages	Percentage living 5 years	Author	Total No. cases all stages	Percentage living 5 years
		Per cent Cases			Per cent Cases
Haagensen & Stout	640	27.0 of 185	Evans and Leucette	175	26.6 of 45
Harrington (1941)	1407	30.4 of 2318	Graves	376	24 of 68

Simmons (M.D.H.)	147	30 of 90	Gratack and Stenstrom	54	51.0 of 54
Simmons (Harrington)	116	5 of 74	Pfahler and Kiefer	35	44 of 93
			Poble and Benson	41	28 of 5
			Richards	120	23.3 of 36
			Westermarck	70	37.0 of 55
			Wiersma	36	27.3 of 56
Average		27.4	Average		27.6

Many of the available records do not indicate the exact number of cases in stage 2 but give only the percentage of "survival" cases in stage 2 and are therefore not used here.

Richards has divided his cases with auxiliary involvement into stages which when combined show approximately 25.5 per cent survival.

The averages of the percentages reported by these authors show greater possibility for 5 year survival when surgery is followed by postoperative irradiation, than when surgery is used alone.

TABLE III.—PATIENTS SYMPTOM FREE 5 YEARS AFTER TREATMENT WITH SURGERY AND BOTH PREOPERATIVE AND POSTOPERATIVE ROENTGEN IRRADIATION FOR CANCER OF THE BREAST STAGE 2

Author	No. cases stage	Stage percentage survival
Abelson, Raabenhorn 1904	20	24
Fickler and Karier	63	52.3
Rosen	5	40.0

Remarks: It is very difficult to compare the results from different clinics because of the difference in classification, difference in technique and difference in the objectives. Recently I have had the privilege of seeing Dr. Gordon Richards at the Radiologic Institute of the Toronto General Hospital and have been deeply impressed with his fine results. He is preparing a paper on this subject and at my request has sent the following personal communication:

I am enclosing herewith chart Table IV which shows the position in connection with our preoperative breast cases as completely as I have been able to analyze the results up to the present. This shows the results of treatment of eighty-two preoperative cases up to and including the year 1930. We have compared these results with one comparative group of typical conventional postoperative cases of approximately the same number which actually was the group of cases treated postoperatively during the year 1929. It might be said that this is unfair but that is a typical group and comparable in size to the preoperative group. Most of the preoperative cases were very advanced and in our own work, instead of the usual classification into three groups or stages, we have broken them down into four groups:

Group 1—Representative of the quite early stage.
Group 2—Moderately advanced but still operable according to the usual criteria.

Group 3—More advanced—borderline of inoperability.

Group 4—Far advanced—agreed by all as inoperable.

Group 5—Indeterminate types or carcinomas associated with metastases.

*It is interesting to me to note that there is fairly substantial improvement in all of these groups and that the patients in Group 5 who survived five years were treated radiologically. Some of the preoperative cases came to operation and of those who did so twenty-five per cent were negative for cancer at operation. Since most of these were quite advanced prior to treatment, I think it speaks well for preoperative treatment.

patients are treated by operation alone or treated by a combination of operation and irradiation.

Classification of cases as to clinical stages 1, 2 and 3 is extremely difficult. It depends

TABLE IV.—PREOPERATIVE COMPARED WITH POSTOPERATIVE ROENTGEN TREATMENT GORDON RICHARDS

Group	Total No. cases C. I. M. Group		Alive or controlled				Odds due to pre- operative therapy Per cent
	Preop- erative	Postop- erative	Preoperative		Postoperative		
			No. of cases	Per cent of total of group	No. of cases	Per cent of total of group	
I		22			20	90	
II	6	20	5	83.3	3	75	8
III		20	7	48.6	13	65	16.5
IV	23	6		27		3	8.6
V	2						12.5
Total	31	48	22		39		

Remarks: It will be observed that Richards has deliberately compared the value of "preoperative" with "postoperative" irradiation, and finds the preoperative superior. In comparing this to our technique, he gives the limit of irradiation preoperatively and is followed after a longer time by operation, superficial like the work reported by Adair, but it will be seen that Richards has produced very serious and convincing results. The results in the indeterminate types of carcinoma associated with metastases are truly remarkable.

upon the experience and clinical judgment of the individual physician or the associated group. We all know that even though we classify those patients having metastases in the axilla as proved by surgery as belonging to stage 2, there is still in this group a considerable variation. The early recognition will depend in part upon the early consultation by the patient and also upon the skill with which lymph nodes are recognized by the physician and the results will depend upon the promptness with which the operation is performed on the one hand and on the other hand the de-

TABLE V.—SUMMARY OF RESULTS IN BREAST CANCER ALL STAGES 1902-1941 SURGERY PLUS POSTOPERATIVE ROENTGEN THERAPY SYMPTOM FREE 5 OR MORE YEARS (PFAHLER) (REVIEW OF THE RECORDS AND TABLE PREPARED BY DR. GEORGE P. KEEFER).

	Total	1902-1911		Total	1912-1921			Total	1922-1931			1932-1941
		Stage	Stage		Stage	Stage	Stage		Stage			
Well 5 years	8	23-66%	19-45%	63	23-71%	18-57%	2-4%	30	8-20%	7-4%	103-57%	
Died carcinoma	63	18	67	35	27			17		14	133	
Died of intercurrent disease	5			9								
Not traced	30			3								
Total all cases	93			26				20			116	

44 per cent of 123 cases in stage 1 treated during 30 years were well 5 years.

51.5 per cent of 18 cases in all stages well 5 years or more.

60 cases of primary carcinoma of the breast treated only by irradiation are not included in above series.

521 cases of recurrent carcinoma of the breast following operation and treatment began more than 6 months after operation and in which there was definite recurrence when first seen by us, are not included in the above analysis.

lay and the more advanced stage in the later cases. Therefore one surgeon may have a more advanced group than another. This will, of course affect the final results both when treated by operation alone and also when treated with operation and irradiation.

In like manner there is a variation to the thoroughness with which various surgeons do the radical or Halsted' operation. One competent surgeon may do his operation in 1 hour and another competent surgeon may take 4 hours. Haagensen and Stout's records show that following operations taking 1 hour or less 28.6 per cent of 56 cases survived 5 years and developed 23.2 per cent local recurrences while of 16 cases taking 4 hours or more gave 56.3 per cent 5 year survivals, and only 12.5 per cent local recurrences. Presumably therefore the long operations are more thorough.

The effects of the preoperative irradiation will depend in part upon the thoroughness and the skill with which each dose is applied and will also be influenced by the relative time of the operation in relation to this preliminary treatment and will be affected in like manner by the skill, amount of irradiation, and time of its application for postoperative roentgen treatment.

The results in the treatment of carcinoma of the breast cannot at present be reduced to mathematical accuracy. Therefore, we are still dependent upon the general impression which in our opinion is favorable to both preoperative and postoperative irradiation but it should be applicable particularly to those cases of carcinoma of the breast associated with palpable lymph nodes, in this group it has been proven that there is a possible error of nearly 30 per cent.

CONCLUSIONS

1. Good results in the treatment of carcinoma of the breast depend primarily upon early recognition, accurate diagnosis and thorough operation.
2. The operative results can be improved by preoperative and postoperative roentgen therapy or by a combination of all three.
3. The good results will depend upon the knowledge, the skill, and the thoroughness with

which each of these therapeutic measures is applied.

4. A review of the results obtained in leading clinics throughout the world confirms the above conclusions.

THE CYSTIC ARTERY AND CONSTITUENTS OF THE
HEPATIC PEDICLE
A Study of

A Study of 500 Specimens

EDWARD H. DASELER, M.D. BARRY J. ANSON Ph.D (Med. Sci.)
WILLIAM C. HAMBLEY M.D., and ARTHUR F. REIMANN M.D. Chicago, Illinois

IN the colic and jejunoileal portions of the digestive tube arterial variation is of a relatively simple order being of the sort encountered in the origin of branches from the trunk of a tree and of twigs from the branches. Simplicity is an adult characteristic of the pattern because developmental change in the small intestine is chiefly one of elongation.

In the arterial supply of the adult liver and the gall bladder certain patterns are preponderant others infrequent. A presentation of the types with record of their frequency should be of interest to the surgeon and to the anatomist.

MATERIALS AND METHODS
course of the

MATERIALS AND METHODS

In the course of the present investigations 500 laboratory specimens were studied consecutively. A sketch was made of each set of vessels. On the basis of these permanent records, types of vascular arrangement were selected. Then for each major type a specimen was selected for illustration. In addition to the types actually encountered several described by other investigators (but not found in the current series) have been figured. These are shown in diagrammatic form (Figs 1 to 79). In order to record relationships of course and caliber of the arteries in this area, 14 specimens were employed for more accurate portrayal of anatomic features.¹

For the convenience of the reader the statistical results of the study have been tabulated (Table I).

OBSERVATIONS AND DISCUSSION

Common hepatic artery The common hepatic artery arose as a branch of the celiac axis (Fig 1) in 83.20 per cent of cases (416 of 500). It was absent (Fig 84) in 12.20 per cent (61 cases). In cases of absence of the common hepatic, the right and left hepatic lobes were supplied by separate arterial branches.

In Figures 80 through 93 the liver has been elevated to expose the inferior surface. peritoneal structures have been removed, but the coexistentness of the biliary pedicle raised to approximating normal interrelationships. In Figure 86 the stomach has been lifted out of the loops to the left. In Figures 87 and 88 the bladder has been lifted out of the loops to the right. In Figure 89 a portion of the jejunum has been cut away and the transected superior mesenteric artery has been similarly retracted.

Contribution No. 459 from the Anatomical Laboratory of Northwestern University Medical School. Paper to be presented, in brief, before the Forum on Fundamental Surgical Problems, the September (1947) meeting of the American College of Surgeons. The comments on the observations of the observer.

[illegible]

TABLE I.—OBSERVATIONS ON ORIGIN AND POSITION OF ARTERIES IN OR NEAR HEPATIC PEDICLE

1. Origin, etc., of common hepatic (or hepatic) artery: 500 cases
 - celiac, 4
 - superior mesenteric, 23
 - aorta, 1
 - absent, 6
2. Origin of right hepatic artery (right ramus of hepatic proper): 500 cases.
 - common hepatic, 416
 - superior mesenteric, 56
 - replacing common hepatic, 23
 - celiac, 4
 - aorta, 1
3. Origin of accessory right hepatic artery: 36 cases.
 - superior mesenteric, 5
 - left hepatic, 3
 - gastroduodenal, 5
 - celiac, 2
 - aorta, 1
4. Origin of left hepatic artery: 500 cases
 - common hepatic, 4
 - celiac, 57
 - replacing common hepatic, 23
 - left gastric, 9
 - gastroduodenal, 1
5. Origin of accessory left hepatic artery: 75 cases
 - right hepatic, 99
 - left gastric, 54
 - common hepatic, 12
 - gastroduodenal, 6
 - celiac, 5
6. Origin of gastroduodenal artery: 500 cases.
 - common hepatic, 377
 - replacing left hepatic, 52
 - right hepatic, 35
 - replacing common hepatic, 9
 - accessory left hepatic, 1
 - celiac, 1
 - absent, 14
7. Origin of right gastric artery: 250 cases.
 - common hepatic, 125
 - left hepatic, 8
 - gastroduodenal, 33
 - right hepatic, 1
 - celiac, 1
8. Origin of cystic artery: 580 cases
 - right division of regular hepatic, 416
 - right hepatic from superior mesenteric, 90
 - left hepatic, 36
 - common hepatic, 6
 - gastroduodenal, 5
 - replacing or accessory right hepatic, 3
 - celiac, 2
 - superior mesenteric, 1
 - superior pancreaticoduodenal, 1
9. Origin of accessory cystic artery: 65 cases
 - right hepatic, 30
 - gastroduodenal, 6
 - common hepatic, 4
 - left hepatic, 3
 - accessory right hepatic from superior mesenteric, 2
10. Origin of single replacing cystic artery: 20 cases
 - replacing right hepatic from superior mesenteric, 36
 - left hepatic, 27
 - right hepatic from replacing common hepatic, 21
 - accessory right hepatic from superior mesenteric, 2
 - common hepatic, 6
 - gastroduodenal, 6
 - accessory right hepatic from celiac, 3
 - celiac, 1
 - superior mesenteric, 1
 - superior pancreaticoduodenal, 1
11. Origin of dual replacing cystic arteries, 15 cases:
 - both from right hepatic branch of superior mesenteric, 7
 - replacing right hepatic and left hepatic, 3
 - both from left hepatic, 1
 - gastroduodenal and accessory right hepatic, 1
 - gastroduodenal and right hepatic branch from celiac, 1
 - gastroduodenal and left hepatic, 1
 - gastroduodenal and right hepatic branch of superior mesenteric, 1
12. Location of hepatic (common hepatic) artery: 419 cases
 - left of common bile duct, 431
 - posterior to same, 7
 - anterior to same, 1
13. Location of right hepatic artery: 500 cases
 - posterior to common hepatic duct, 325
 - anterior to common hepatic duct, 38
 - posterior to common bile duct, 58
 - right of duct system, 1
 - posterior to right and left hepatic ducts, 8
 - left of duct system, 8
 - anterior to common bile duct, 7
 - anterior to right and left hepatic ducts, 4
14. Location of cystic artery: 580 vessels
 - Chalot's triangle, 405
 - anterior to common hepatic duct, 1
 - anterior to common bile duct, 17
 - posterior to common hepatic duct, 2
 - between hepatic ducts, 6
 - anterior to cystic duct and right hepatic duct, 6
 - right of duct system, 5
 - posterior to common bile duct, 3
 - left of duct system, 1
 - posterior to cystic duct and right hepatic duct, 1

A replacing type of common hepatic artery was present (Fig 93) in 4.6 per cent of specimens (23 cases). In almost all instances (22 of 23) the replacing vessel was derived from the superior mesenteric artery (1 from aorta).

In 81.54 per cent of the cases (358 of 439 studied) the common hepatic artery was a long trunk which did not break up into its hepatic

branches until it had come within 4 centimeters of reaching the liver surface (Fig 88). In 18.46 per cent (81 cases) the artery was short and divided into hepatic branches that ascended as separate trunks for a distance of more than 4 centimeters (Fig 87).

Regarding relation to the biliary duct system it may be said that in 98.1 per cent of the

specimens (431 of the 439) the common hepatic artery coursed entirely to the left of the common bile duct (Fig 88). In only 1.6 per cent (7 cases) the artery crossed posterior to the common bile duct, in 0.2 per cent (1 case) it crossed the common duct anteriorly in 0.4 per cent (2 cases) it crossed posterior to the cystic duct before dividing into its terminal right and left hepatic branches.

Right hepatic artery. A normal right hepatic artery (i.e., one which supplies the right lobe of the liver after origin from a normal common hepatic artery as in Fig 80) was present in 83.2 per cent of the cases (416 of 500).

A replacing type of right hepatic artery (i.e., one by which the right lobe is supplied from other than the above-mentioned source) was present in 16.8 per cent (84 cases). In 11.2 per cent (56 cases) the vessel supplying the right hepatic lobe originated from the superior mesenteric artery (Fig 5) while in 1 case (Fig 9) it arose from the aorta. In 4.4 per cent (22 cases) the right hepatic lobe was supplied by the right hepatic branch of a common hepatic artery derived from the superior mesenteric artery (Fig 12), while in 0.2 per cent (1 case) the common hepatic artery arose directly from the aorta (Fig 8). In 0.8 per cent (4 cases) the right hepatic artery arose as a direct branch of the celiac axis (Fig 13), independent of the left hepatic branch.

Accessory right hepatic arteries supplying the right hepatic lobe additive to a normal or replacing artery, occurred with an incidence of 7.2 per cent (36 cases). In 3 per cent (15 cases) the accessory right hepatic artery arose as a branch of the superior mesenteric artery (Fig 6) in 2.6 per cent (13 cases) as a branch of the left hepatic artery (Fig 15) in 1 per cent (5 cases) from the gastroduodenal artery (Fig 11) in 0.4 per cent (2 cases) from the celiac axis (Fig 14) and in only 0.2 per cent (1 case) directly from the aorta (Fig 10).

The location and course of the right hepatic artery are subject to considerable variation. In 65 per cent (325 cases) the artery crossed from left to right posterior to the common hepatic duct (Fig 80) in 3.6 per cent (18 cases) it crossed posterior to the right and left hepatic ducts at a level higher than their juncture. In 11.6 per cent (58 cases) the right hepatic

Figs. 1 to 3. Common hepatic artery (*arteria hepatica*, BNA) variations in origin shown diagrammatically. Abbreviations (Figs. 1 to 79): ALH accessory left hepatic artery; ARH accessory right hepatic; C cystic; CA, celiac axis; GD gastroduodenal; LG left gastric; LH, left hepatic; RG, right gastric; RH right hepatic; RRU replacing right hepatic; S splenic; SM superior mesenteric.

artery crossed anterior to the common hepatic duct (Fig 83) while in only 0.8 per cent (4 cases) it crossed anterior to the right and left hepatic ducts above their point of union. In 11.6 per cent of the specimens (58 cases) the right hepatic artery crossed posterior to the common bile duct (Fig 84) in 1.4 per cent (7 cases) it crossed the common duct anteriorly (Fig 87). In 4.4 per cent (22 specimens) the same artery coursed entirely to the right of the common bile duct and hepatic ducts in 1.6 per cent (8 cases) entirely to the left thereof. In 11.4 per cent (57 cases) the artery crossed posterior to the cystic duct (Fig 87) while in 0.8 per cent (4 cases) it crossed the cystic duct anteriorly.

Left hepatic artery. A normal left hepatic artery (i.e., one which originates from a normal common hepatic artery and supplies the left lobe of the liver, as in Fig 89) occurred in 82 per cent of the specimens (410 of 500). In 1.4 per cent (7 cases) the artery crossed anterior to the right hepatic artery in 0.4 per cent (2 cases) posterior to it.

A replacing type of left hepatic artery occurred in 18 per cent of the specimens (90 of the 500 cases). In 11.4 per cent (57 cases) this artery arose directly from the celiac axis (Figs. 20 and 25) in 1.8 per cent (9 cases) from the left gastric artery (Fig 23), in 4.4 per cent (22 cases) from a replacing type of common hepatic artery which in turn arose from the superior mesenteric artery (Fig 22) in 0.2 per cent (1 case) it was a branch of a replacing type of common hepatic artery which in turn arose as a direct branch of the aorta (Fig 19) and in

Fig. 4 to 15. Right hepatic artery (*ramus dexter of a. hepatica propria*) variations in origin, diagrammatic.

patric artery arising in the angle termed Chalat's triangle, formed by the common hepatic and cystic ducts (Fig 83). This arrangement obtained in 69.8 per cent of the cases (405 of 580 cystic arteries). The cystic artery crossed ventral to the common hepatic duct (Fig 81) in 21.2 per cent of the cases (123 of 580) dorsal thereto in 2 per cent (12 specimens). The artery crossed ventral to the common bile duct (Fig 88) in 3 per cent (17 cases), dorsal to the duct (Fig 90) in 0.52 per cent (3 cases). In 1.05 per cent (6 specimens) the cystic artery arose from the right hepatic artery in the interval between the right and left hepatic ducts then coursed from left to right crossing the right hepatic duct anteriorly to reach the gall bladder. In 1.05 per cent (6 cases) the artery arose entirely to the right of the duct system and coursed superiorly to cross the cystic duct anteriorly before reaching the gall bladder. In 0.17 per cent (1 case) encountered the artery crossed posterior to the cystic duct (Fig 90). In 1 per cent (5 cases) it arose and coursed entirely to the right of the duct

system, crossing neither the common hepatic, cystic, or common bile ducts (Fig 86). In 0.34 per cent (2 cases) the cystic artery arose as a branch of the right hepatic artery within the portal fissure, from which high point it crossed ventral to the right and left hepatic ducts enroute to the gall bladder.

A single replacing type of cystic artery occurred in 20.8 per cent (120 cases) of the total number of arteries (580). The origin of this vessel was extremely variable. In 30 per cent of these cases (36 specimens) it arose from a replacing type of right hepatic artery derived from the superior mesenteric artery (Fig 84) in 22.5 per cent (27 cases) from the left hepatic artery (Fig 85) in 17.5 per cent (20 specimens) from the right hepatic branch of a replacing type of common hepatic artery derived from the superior mesenteric artery (Fig 93) in 9.10 per cent (11 specimens) from the common hepatic artery (Figs. 69 and 72) in 10 per cent (12 cases) from an accessory right hepatic branch of the superior mesenteric artery (Fig 74) in 5 per cent (6 cases) from the gas

Figs. 31 to 45. Gastroduodenal artery (*gastroduodenalis*) variations in origin, diagrammatic.

proximal portion of that vessel. Then an origin from the distal portion of the hepatic artery proper before division into right and left hepatic arteries would be expected to follow in frequency after that an origin from the left hepatic artery. Further migration down the arterial tree would bring the cystic to arise as a branch of the gastroduodenal artery. Next would be origin as a branch of the common hepatic artery near the latter's source from the celiac axis then derivation from the celiac itself with a long devious course to the gall bladder. Spatially more remote would be a right or accessory right hepatic artery arising not from the celiac axis or common hepatic arteries but from the superior mesenteric; the cystic branch then being derived from the terminal portion of such an anomalous right hepatic artery. When the common hepatic artery and its branches arise from the proximal portion of the superior mesenteric artery or from the aorta itself the cystic artery could be

derived from any portion or branch of this common hepatic trunk but the most common source would be expected to be the terminal portion of the right hepatic artery. A right hepatic artery derived as a separate and distinct branch from the celiac axis would be regarded as rare. A cystic branch of this anomalous vessel is to be expected in the majority of such cases. Migration downward toward the source branch derived of the aorta or even from the axial vessel itself could be expected as less frequent patterns; the cystic thus arising from the celiac superior mesenteric or aorta itself. In rare instances origin could conceivably take place from the terminal gastroduodenal branches; the right gastroepiploic and superior pancreaticoduodenal arteries or even from a supraduodenal branch of hepatic or gastroduodenal origin.

Actually in the 500 specimens examined examples of all but three of the predictable variations of the cystic artery were seen.

Fig. 46 to 66 Right gastric artery (a. gastrica dextra) variations in origin, diagrammatic.

portal vein before ascending to the right of these structures to reach the gall bladder and its fossa. In 81 per cent (13 of the 16) the cystic artery arose from the common hepatic artery near its bifurcation into right and left hepatic arteries (Fig 60) while in 19 per cent (the remaining 3 cases) it formed a long slender branch arising from the proximal portion of the common hepatic artery (Fig 72).

Type VI The cystic artery took origin from the gastroduodenal artery (Figs. 71 and 88) in 2.6 per cent of the cases (15 of 580). In 73.3 per cent of these (11 of the 15) the cystic artery arose from the proximal portion of the gastroduodenal artery lying to the left of the common bile duct. In all of these instances the cystic artery was long and slender. In only 1 case did the artery ascend to the left

of the common bile duct in the others it crossed the duct anteriorly attaining its right side before ascending to the gall bladder. In 53.3 per cent (8 of the 15 cases) there was an additional cystic artery present derived from a source other than the gastroduodenal artery.

Type VII In only 0.4 per cent (2 cases) in the present series the cystic artery arose as a branch of the celiac axis (Fig 73). In both specimens it was a long slender twing which crossed to the right, posterior to the common bile duct and portal vein then ascending on their right to reach the gall bladder. In both cases the artery formed the sole source of supply to the gall bladder.

Type VIII In 3 cases in the present series (0.6 per cent) the cystic artery was derived from a replacing or from an accessory type of

right hepatic artery the latter derived in turn from a source other than the superior mesenteric artery. In several specimens the right hepatic artery arose as a branch of the celiac axis.

Type IV. In but 0.2 per cent of the specimens (1 case) the sole source of arterial supply to the gall bladder was a long slender cystic artery derived from the first portion of the superior mesenteric artery (Figs 76 and 90). In ascending it crossed posterior to the duodenum, pancreas, portal vein and common bile duct, to attain the right side of the hepatic pedicle, and then to pass upward beneath the cystic duct to the gall bladder.

Type V. In 0.2 per cent (1 case) the cystic artery took origin from the superior pancreaticoduodenal (Fig. 19). The artery was long and slender arising to the right of the common bile duct, it passed almost vertically upward to the gall bladder.

Type VI. Lipschutz has reported 2 cases in which the cystic artery originated as a direct branch from the aorta (Fig. 11). Examples of such an unusual origin were not encountered in the present series.

Type VII. A single case has been reported by Kosinski in which the cystic artery arose as a branch of the right gastroepiploic artery (Fig. 78). No such specimens were encountered in the present series.

Origin of the cystic artery from any arterial branch arising to the left of the abdominal aorta has not been reported by others or seen by the present authors.

Double and triple cystic arteries. Doubling of the cystic artery is relatively common, occurring in 15.6 per cent of the cases (78 of 500). The source of these dual cystic arterial branches is quite variable. Both branches (Fig. 82) are most commonly derived from the right hepatic artery (57 cases). However branches from the left hepatic (Fig. 88) from the common hepatic and from the gastroduodenal arteries (Figs. 86 and 88) also occur in a decreasing order of frequency.

In a single specimen of the current series, three cystic arteries were present, all branching from the right hepatic artery: two arose to the right of the common hepatic duct after the source vessel had crossed beneath the duct.

the third, coming from the right hepatic artery to the left of the common hepatic duct, crossed anterior to the duct to supply the anterior surface of the gall bladder. Two such cases have been reported previously one by Brewer and one by Browne, making a total of only 3 cases in almost 2000 specimens examined.

In one specimen, representing a type not previously described, two cystic arteries were present, the first derived from the left hepatic artery near the bifurcation of the common hepatic artery the second from the right hepatic artery just beyond the point of crossing behind the common hepatic duct (Fig. 89). The two cystic arteries then fused to form a common trunk which coursed along the upper and posterior border of the cystic duct to the neck of the gall bladder where the conjoined channel again divided into branches supplying both surfaces of the gall bladder and its fossa.

To facilitate our study of the hepatic pedicle the authors have endeavored to depict the sources from which the common right and left hepatic, gastroduodenal and right gastric arteries might theoretically arise. Diagrammatic Figures 1 through 66 serve this purpose.

The common hepatic artery may be derived from the celiac axis (Fig. 1) the aorta (Fig. 2) or the superior mesenteric artery (Fig. 3). When the common hepatic artery is absent, the right and left hepatic arteries may arise from other sources (Figs. 5, 9 and 13).

The right hepatic artery may arise as a branch of a normal or replacing type of common hepatic artery from the superior mesenteric artery, aorta, celiac axis, left hepatic, or gastroduodenal arteries (Figs. 4 through 15).

The left hepatic artery may arise as a branch of a normal or of a replacing common hepatic artery, a replacing type of left hepatic artery may arise as a branch of the aorta, celiac axis, left gastric, splenic, or gastroduodenal arteries. Accessory left hepatic arteries may arise as branches of the common hepatic, right hepatic, left gastric, aorta, celiac axis, splenic or gastroduodenal arteries (Figs. 16 through 30).

The gastroduodenal artery may arise as a branch of a normal or replacing common hepatic artery or it may also arise from any of the following arteries: the celiac axis replacing

Figs. 67 to 79. Cystic artery (*a. cystica*) variations in origin, diagrammatic. In addition to the origins here depicted, the cystic also arose in 3 instances from an accessory or a replacing type of right hepatic artery the latter derived in turn, from the celiac (bringing the total number of cystic arteries studied to 580)

or accessory left hepatic, replacing or accessory right hepatic or the aorta (Figs. 31 through 45).

The right gastric artery may be derived as a branch from a normal or replacing common hepatic artery as a branch of a normal replacing or accessory right or left hepatic artery as a branch of a normal replacing or accessory gastroduodenal artery or as a direct branch of the celiac axis or abdominal aorta (Figs. 46 through 66).

Selected cases While types of arterial source and branching may be conveniently shown by simplified diagrams (Figs. 1 through 79) pictorial records of actual specimens are required for full appreciation of the precise form course and relations of surgically important structures.

Some selected and to a degree typical cases will be discussed in association with drawings prepared in the dissection room.

Figure 80. The cystic artery arose from the right hepatic artery in the angle bounded by the cystic and common hepatic ducts. gall bladder retracted to the left. The right hepatic artery crossed posterior to the common hepatic duct, where it gave rise to a small branch which entwined the common bile duct.

Figure 81. The cystic artery arose from the proximal portion of the right hepatic artery to the left of the common hepatic duct. It crossed the hepatic duct anteriorly after giving off a small branch to the quadrate lobe of the liver. It coursed along the anterosuperior border of the cystic duct to the gall bladder.

Figure 82. The larger of two cystic arteries arose from the right hepatic artery after the latter had crossed posterior to the common hepatic duct dividing immediately upon reaching the gall bladder its

Figs. 80 to 86. Constituents of the hepatic pedicle; prepared from individual dissections.

branches supplied the anterior surfaces of the gall bladder and right half of its fossa. The other cystic artery arose from the right hepatic artery to the left of the common hepatic duct; supplying two small twigs to the quadrate lobe. It then coursed to the right crossing posterior to the hepatic duct to supply the hepatic surface of the gall bladder and the left half of its fossa.

Figure 83: The cystic artery arose to the right of the common hepatic duct from a right hepatic artery which crossed anterior to the common hepatic duct.

Figure 84: A common hepatic artery is wanting. The left hepatic artery arose as a branch of the

celiac axis, coursing upward to the left of the common bile and hepatic ducts. It lay on the anterior surface of the portal vein. The right hepatic artery derived from the first portion of the superior mesenteric artery passed obliquely upward and to the right, first posterior to the portal vein and common bile duct, and then to the right of the common bile duct. Just before entering the right hepatic lobe it gave rise to a large cystic branch to the hepatic surface of the gall bladder.

Figure 85: The cystic artery originated from the proximal portion of the left hepatic. It then coursed transversely from left to right, lying in close associa-

Fig. 95. Constituents of the hepatic pedicle, cooccluded.

to the gastroduodenal artery before ascending to the right of the common bile and hepatic ducts. It gave rise to the cystic artery and then passed posterior to the cystic duct to enter the right hepatic lobe.

Figure 88 The cystic artery arose as a branch of the gastroduodenal. Coursing vertically upward, it crossed anterior to the common bile duct to reach the right half of the gall bladder and adjacent portion of the fovea. A second cystic branch of the left hepatic artery was also present. It coursed transversely from left to right crossing anterior to the common hepatic duct to supply the left half of the gall bladder and fovea. This vessel closely matched the cystic duct in its course while the gastroduodenal branch similarly accompanied the common bile duct.

Figure 89 A rare example of dual cystic arteries, fused distally to form a single terminal trunk. The larger and longer branch was derived from the left hepatic artery near its origin. Crossing anterior to the common hepatic duct, it fused with the second cystic branch derived from the right hepatic artery in the triangle of Calot. The common trunk then coursed along the posterolateral border of the cystic duct to the neck of the gall bladder and there divided into its terminal branches.

Figure 90 The cystic artery derived from the proximal part of the superior mesenteric, crossed posterior to the portal vein and common bile duct to ascend to the right of the latter structure. Near its termination the artery passed in an upward direction beneath the cystic duct to reach the neck of the gall bladder.

Figure 91 A large accessory right hepatic duct entered the common bile duct just distal to that of fusion of the cystic and common hepatic ducts. The cystic artery was derived from the right hepatic artery after the latter had crossed posterior to the common hepatic duct.

Figure 92 The cystic duct drained directly into the right hepatic duct (the common hepatic duct being absent). The cystic artery arose as a branch of the most proximal portion of the right hepatic artery. It crossed in front of the right and left hepatic ducts to reach the gall bladder.

Figure 93 A short common hepatic artery from the superior mesenteric divided into right and left hepatic branches. The right branch crossed posterior to the common bile duct and portal vein, and then ascended to the right of these structures crossing posterior to the cystic duct before giving off a short cystic branch and dividing into its two terminal branches. The left branch ascended to the left of the common bile duct and portal vein passing posterior to the splenic vein before giving rise to a large gastroduodenal and small right gastric artery. Terminally it divided into two terminal branches to the liver hilum.

B. BILIARY DUCT SYSTEM

In their major features, the extrabiliary ducts and the gall bladder are remarkably constant. Boyden (1926) in a survey involving 10 000 domestic animals and 19 000 cadavers found comparatively few major variations. Chief among these were the following: (1) cleft gall bladders which originate by subdivision of the primary cystic diverticulum (2) diverticular bladders (vesicles or subordinate lobes which arise as buds from the neck of the embryonic gall bladder) (3) ductular bladders (supernumerary vesicles derived from either the hepatic, cystic or common bile ducts and encountered chiefly in humans) (4) trabecular bladders (vesicular outgrowths of the liver trabeculae bordering the gall bladder fossa and occurring as rare anomalies of cattle sheep and perhaps humans) (5) pancreatic bladder (a rare anomaly originating as an outgrowth from the pancreatic tissues occurring in the cat).

Embryologically the biliary duct anomalies encountered in the present study can best be explained on the basis of changes occurring in the hepatic antrum, a dilatation or vestibule at the upper end of the embryonic choledochus into which all the ducts of the liver including the cystic duct, empty. In the present series (500 cases) only 12 major anomalies of the

duct system were encountered an incidence of but 2.4 per cent. This figure is astonishingly low when compared with the large number of extreme variations in the vascular supply.

In a single specimen (Fig. 91) an accessory right hepatic duct entered the common bile duct 5 millimeters distal to the junction of the cystic and common hepatic ducts. In three specimens encountered, the common hepatic duct was wanting, the cystic duct draining directly into the right hepatic duct (Fig. 92). Three examples of an accessory right hepatic duct which drained into the cystic duct were seen. Two cases of cholecystohepatic duct in which a small accessory duct from the right hepatic lobe drained directly into the gall bladder, were met with, a small hepatic duct from the right or quadrate lobes of the liver which drained into the common hepatic duct in addition to the regular right and left hepatic ducts was encountered twice. In a single case the cystic, right and left hepatic ducts joined together at a common point of fusion so that no common hepatic duct existed.

Three modes of union of the cystic and common hepatic ducts have been described by Eusendath (1920) the angular the parallel and the spiral. All three modes of union were encountered with varying frequency in the present series but such variations were not considered as major anomalies of the duct system and were therefore not recorded.

SURGICAL COMMENTARY

The increasing number of operations performed for obstructive jaundice and biliary fistula due to man made injuries of the common bile duct and the hepatic ducts calls for a more detailed knowledge of the blood vessels in the gastrohepatic region. The degree of variation in the vascular pattern encountered in this area is of vital importance to the surgeon concerned with the techniques employed in radical pancreaticoduodenectomy. Dennis and Varco (1946) have described a case of carcinoma in the head of the pancreas associated with a hepatic artery which arose from the superior mesenteric artery and traversed the head of the neoplastic gland. Pancreaticoduodenectomy was performed an operation which necessitated resection and reanastomosis of

the hepatic artery. The patient, however, failed to survive this procedure.

Since variations in the biliary tree and its associated vascular elements are so frequent, it is advisable to identify major structures in this area before surgery is attempted. Adequate exposure is essential. Introduction of the hand between the right hepatic lobe and the diaphragm will allow air to come between these surfaces, by this means the right lobe is pushed downward into lower abdominal position. If necessary greater mobilization of the liver can be obtained by cutting the round ligament and its falciform investment between ligatures.

In the performance of cholecystectomy the cystic duct should be carefully dissected from the adjacent fibrous and fatty tissue in order to expose its full course from the gall bladder to juncture with the common hepatic duct. McWhorter (1923) is of the opinion that exposure may be facilitated by incising the peritoneum along the right side of the body of the gall bladder. Then by lifting and rotating the gall bladder to the left, it may be peeled away from the liver. The left peritoneal fold with its contained cystic arterial branches, is thus readily freed. Identification of the cystic duct and artery is often rendered difficult by adhesions and by adjacent areas of inflammation.

The observations herein recorded point to the hazard of ligating the cystic artery and duct with a single tie. The course of the cystic artery is so variable and the occurrence of dual branches so common that careful examination of the fatty tissue immediately behind the cystic duct, with separate ligation of the artery seems essential. Ligation of the cystic duct at a point 1 to 2 centimeters proximal to its juncture with the common hepatic and bile ducts is also advisable. Unless this precaution is taken, tenting of the duct with pinching of its wall by the ligature can easily result.

Jackson (1938) stated that the major cause of injury to the ducts is hemorrhage from divided cystic artery or an anomalous stump. He believes that the surest way to avoid this danger is to proceed in such a way as to identify and ligate the cystic artery before dividing the cystic duct. He feels that

because the artery frequently is anomalous in position, is often larger than expected, and is not uncommonly multiple, it is important to clamp divide and ligate all tissues of the area, as if it were actually established that such anomalies were present. In the presence of cystic arterial hemorrhage, he has outlined the steps necessary to control bleeding chiefly by means of pressure on the common hepatic trunk (with the index finger inserted into the epiploic foramen).

Elsendrath (1918) has emphasized the frequency with which the right hepatic artery lies in close approximation to the cystic duct (cf current Figs. 80 81 85 87 and 88). Such position renders the artery particularly vulnerable to injury during cholecystectomy whether the dissection begins at the fundus of the gall bladder or at the cystic duct.

In choledochotomy the common occurrence of vessels intimately associated with the common bile duct would be taken into account (Figs. 80 84, 85 87 88 89 and 93). Injury to these structures may result in troublesome hemorrhage and subsequent injury to the common bile or hepatic ducts or even in inadvertent ligation of the right or common hepatic arteries with resultant hepatic infarction necrosis and so called liver death. In recent years opinion has been divided as to whether or not true infarction and necrosis would result, in man, from ligation of the right, of the left, or even of the common hepatic artery. Certainly the major portion of blood going to the liver is carried by way of the portal system. This, however is venous blood with a low oxygen content. It is evident from the present study that before a dependable conclusion can be reached the physiological importance of the frequently occurring hepatic arteries (of both replacing and accessory types) must be determined. In any event the surgeon should ascertain whether such vessels exist before undertaking ligation of the hepatic arteries.

Variations in the duct system although rare in man can be the basis of serious and even fatal complications. Severance of an anomalous hepatic duct (Fig. 91) would result in bile peritonitis. This complication is especially likely to occur when small accessory bile ducts

drain into the cystic duct or directly into the gall bladder. Neuhoff and Bloomfield (1945) have reported two cases of cholecystohepatic duct. In one of the cases failure to ligate caused a biliary fistula of 45 days duration. One of the present authors has seen three additional instances of this anomalous duct.

The surgeon might readily encounter difficulty in identifying and exposing the common bile duct. It has been regularly taught that this structure is sufficiently avascular in its supraduodenal portion to allow safe exposure by incision through the overlying peritoneum. However the fallacy of such teaching becomes evident when it is remembered that the right hepatic artery (7 cases) or the cystic artery (17 cases) may cross anterior to the common bile duct, and that small arterial branches accompany and entwine the duct (Figs. 80 85 and 88). The frequent occurrence of a major arterial trunk situated to the right of the common duct (90 cases) calls for extreme caution in exposing the duct from this approach. Preliminary palpation, and if necessary exploration by aspiration (with a syringe and small needle) is advisable. Certainly before any procedure involving the biliary ducts is attempted, a thorough search for anomalous hepatic vessels and their branches is surgically desirable (Figs. 80 84, 85 87 and 93).

SUMMARY

1. In a study of 500 cadavers the arterial patterns and modes of variation of the common hepatic artery and its branches have been reported.

2. The relationship of these arterial trunks and branches to the biliary ducts have likewise been reviewed in detail.

3. On the basis of site of origin, the cystic artery has been classified into 12 types and their number and percentages of occurrence recorded.

4. Two rare and unusual patterns of cystic arterial variation triplication and fusion, have been presented.

5. A brief résumé has been made of the abnormalities encountered in the biliary duct system.

6. The application of these findings to the surgery of the gall bladder common bile duct,

pancreas and duodenum has been discussed. Recommendations have been made which should facilitate detection of anomalous vessels and ducts and as a consequence aid in protecting such structures from inadvertent surgical trauma.

AIR ARTHROGRAPHY OF THE KNEE JOINT

J G BONNIN Lieutenant Colonel R.A.M.C., and J L BOLDERO Captain, R.A.M.C.,
Islip Oxford, England

RECENTLY there has been a series of papers on air arthrography or pneumoroentgenography as the Americans prefer to call it, of the knee joint. This appears to indicate a revived interest in a method which is now many years old and as far as cartilage injuries have been concerned it has been the general custom to belittle. True, the experienced few have found it of great assistance but there has been no general acknowledgment of its value as an ancillary method of investigation. The conditions under which we were working suggested that its employment might be of value as owing to language difficulties the detailed history so necessary to an accurate diagnosis could not be obtained from many Indian troops. They themselves lacked the vocabulary and the observation to describe accurately what they felt, and the interpreters available acted more as a baffle than a link between the surgeon and the patient. A short cut to accurate diagnosis, if available, was thus desirable and it was decided to explore the value of air arthrography.

There was also the usual series of doubtful cases in British troops in whom positive or negative evidence by an ancillary method would be of value in helping to decide immediate disposal. In order to obtain the necessary experience in the method it was decided to submit all patients, whether or not a diagnosis could be made clinically, to air arthrography to obtain in particular the benefit of comparing the arthrographic findings with those at operation.

Commenced with open views as to its value, and in an experimental frame of mind the method, in our hands has grown to be extremely reliable, and a very valuable addition to the line of investigation. This is due in part to an improvement in technique and in part to increased experience in the interpretation of the roentgenograms. Unquestionably the most important factor in the accuracy of the

method is the quality of the roentgenogram produced, and it is probable that the poor opinion of the method often expressed is due to the defective films submitted for interpretation.

METHOD

After a 24 hour preparation of the knee, the patient is taken to the theater and, under full aseptic precautions, the joint is filled with air. As much air as possible is introduced and the quantity which can be introduced varies markedly from knee to knee the more air introduced, of course, the better the visualization of the cartilage produced. At first, an filtered room air was used and a device was arranged to introduce air filtered through cotton wool. No reaction, however having occurred in the early cases the use of unfiltered room air has been continued with no untoward results. The delay in the absorption of the air from the joint is both an advantage and a disadvantage an advantage in that filling a disadvantage in that it takes 5 days for the air to absorb and the physical signs in the joint are obscured during this period though the patient is in no discomfort. It has become our practice, however to follow the arthrography where positive by arthrotomy 2 days later thus effectively removing the air. Under local anesthesia and by means of a lateral approach to the suprapatellar pouch the joint is first emptied of any effusion, and then filled with air. At first in order to minimize discomfort, a few cubic centimeters of novocain were introduced into the joint, but it was found that there was little pain from the introduction of the air the most painful part being the infiltration of the synovial membrane with the anesthetic, and this was discontinued. It is not always as easy as it appears to enter an undistended suprapatellar pouch the size of which varies enormously from patient to patient. A small amount of effusion makes the puncture much easier but complicates the

up the compartment under investigation the rays being directed roughly horizontal to the table top. The obliquity of the views is judged by eye as near as possible to those shown in Figure 2 in which it will be noticed that they vary for each meniscus. A long dental cone throwing a 5 inch diameter field at 24 inches, is used and care is taken to see that the tibial spines are included in the field. Two and a quarter seconds exposure is used with intensifying screens, and blue brand or red seal film at 15 milliamperes and 47 kilovolt peak.

NORMAL CARTILAGE APPEARANCE

Lateral meniscus. This is attached antero-laterally to the joint capsule at the level of the lower end of the femur so that the arthrograph of the anterior horn shows a large air space under the cartilage, the shadow of which passes downward and medially and tapers off evenly toward the center of the joint (Fig. 3). Laterally the attachment is a little thinner than the cartilage itself but once between the

bones the cartilage tapers off smoothly as before (Fig. 4).

Posterolaterally and posteriorly the air in the sheath of the tendon of popliteus, which separates the outer edge of the meniscus from the fibula collateral ligament, complicates the picture. The cartilage insertion appears wider and a semicircle of air concave medially is seen crossing it a little medial to its insertion (Fig. 5). More posteriorly the air shadow becomes concave laterally and lies actually in the insertion of the cartilage to the joint capsule the cartilage thus being attached by two fine bands, one above and one below the sheath (Fig. 6). In these posterior oblique views and occasionally in the true anteroposterior view the anterior horn of the cartilage may be seen curving up behind the femoral condyle and then down again as it tapers off toward its medial attachment.

Medial meniscus. The shadows thrown by this cartilage are less complicated than those of the lateral. Anteriorly the meniscus has a

narrow attachment widens a little and then narrows to a point thus appearing to have an oval shape in cross-section. Passing laterally its attachment widens to the same thickness as the cartilage itself the shadow of which now tapers off smoothly across the joint. Posteriorly the attachment is wider than the cartilage the body of which tapers evenly as it passes between the condyles of the two bones.

CRITERIA OF ABNORMALITY NOTED

Lateral meniscus The complexity of the shadows cast by this cartilage until its peculiarities are mastered makes diagnosis of lesions more difficult than those of medial meniscus.

The following points were noted in connection with the abnormal lateral cartilage (1) irregularity of the cartilage surfaces (Figs 10 and 11) in cases of tags and reduced 'bucket handles' (2) additional shadows in the lateral or medial compartments of the joint (Fig 12)

in cases of displaced portions of cartilage or 'bucket handles' (3) extension or widening of the air space between the cartilage and the tendon of popliteus (Fig 13) in posterior tears (4) loss of any substance from the cartilage in displaced tears and 'bucket handles' (5) thickening of cartilage insertion to joint capsule in cases of cyst formation (Fig 14).

Lack of alignment of lateral edge of femoral and tibial condyles is common and is not considered by us of any diagnostic significance.

Medial meniscus The following points are noted in connection with the medial meniscus (1) loss of substance from the cartilage with or without extra shadows in the medial compartment of the joint indicating displaced 'bucket handle' (Figs. 15 and 16) (2) irregularity of either surface of the cartilage (Fig 17) (3) fine linear air spaces in the cartilage indicating undisplaced tears which may be partial or complete (Fig 18) (4) thickening of the

insertion as in the lateral cartilage indicating cyst formation (5) increase in distance between meniscus and articular cartilages peripherally indicating ligamentous rupture (Fig 20)

Fig. 20.

Fig. 20a.

Fig. 20. Rupture of medial collateral ligament showing escape of air round both upper and lower attachment.

Fig. 20a. Rupture of the medial collateral ligament, showing escape of air round its lower attachment.

Air arthrography by throwing up the shadows of the normally invisible cartilaginous layer on the condyles makes possible the diagnosis of cartilaginous damage with which no

bony damage is associated (Fig 12) This may be of value in early traumatic arthritis, and would produce a more convincing picture of the early stages of osteochondritis dissecans.

A few cases of rupture of the collateral ligaments of the knee have been arthrographed information of some value as to the site of rupture of the ligament and the question of associated cartilage damage may be obtained. The surgeon who considers operation advisable in those cases in which the rupture is severe and permits more than slight opening of the joint, will gain considerable information as to the level of the rupture (which may be at the tibial attachment, the femoral attachment opposite the joint line or scattered through different layers at different levels) and so be able to center his incision more accurately.

Sufficient work has not yet been done to obtain the full roentgenological picture in the various types of rupture, but we believe this has interesting possibilities.

In intra articular fractures, the method has not been used owing to the danger of air embolism when cortical bone is opened up.

CASES IN WHICH AIR ARTHROGRAPHY IS UNLIKELY TO BE OF VALUE

As air arthrography only shows the shadow of the cartilage, detachments of the anterior and posterior horns in which the shape of the cartilage remains the same may be overlooked. These conditions are, however, rare, and the so called 'hypermobile cartilage' is a lesion which it is difficult to prove scientifically and which must be carefully considered as it proves such an easy refuge for the careless surgeon. One case in our series had a detached anterior horn held in position by the soft tissues which was not diagnosed together with a hypertrophic fatty pad.

Hypertrophic fatty pads are also impossible to diagnose roentgenologically but a normal cartilage, shown by air arthrography together with the characteristic story of giving without locking click or severe reaction may assist in a preoperative diagnosis. The knowledge that the posterior half of the cartilage is normal is also of value in giving the surgeon confidence in a decision to leave the cartilage behind when no cartilage lesion is found at operation.

and there is some doubt whether the fatty pad lesion is the cause of the trouble.

Very fine 'bucket handle' tears may be difficult to visualize, but we have demonstrated lesions where the 'bucket handle' was no more than $\frac{1}{8}$ inch thick. Small tags have also been shown (Fig 10) but it is admitted that their successful demonstration depends to some extent, on their position and it would be possible to overlook them. We have shown that the transverse tear, more often operative than traumatic, may be demonstrated.

RESULTS

The object of this article has been to prove the case with which satisfactory views of the menisci can be obtained by arthrography and particularly with the technique described and their value in diagnosis. The accurate relationship of the method to diagnosis, from a statistical viewpoint, is however, very hard to prove and with the limited number of cases available to us can only lead us to very general conclusions. It is manifestly impossible to submit all negative findings to operation it is in the negative cases that the possibility of roentgenological error remains unchecked.

RESULTS IN 75 CASES ARTHROGRAPHED

Ruptured medial collateral ligaments	3
Cysts of the external cartilage, with tears	3
Clinically and roentgenologically torn, refused operation	3
Clinically torn, roentgenologically confirmed operatively torn	35
Clinically doubtful, roentgenologically proved, operatively torn	5
Clinically torn, roentgenologically normal, operatively torn	3
Clinically doubtful, roentgenologically negative operatively normal	2
Clinically doubtful, roentgenologically negative, operatively torn	2
Clinically doubtful, roentgenologically negative, hypertrophic fatty pads	2
Clinically doubtful, roentgenologically negative, returned to unit	17

Thus in 44 out of 49 cases operated upon the roentgenological findings were confirmed operatively. In two of these a negative arthrography was confirmed by the discovery of a normal cartilage, and the presence of a degenerative arthritis. These 2 cases occurred in the early stages of the investigation when due weight was not given to the roentgenolog-

ical findings, which in these cases would have enabled one to avoid an undesirable operation. In 2 other cases the clinical findings were considered to justify operation, in spite of a negative arthrography. In both cases, a normal cartilage was found, and a hypertrophic fatty pad was apparently the cause of the symptoms. One of these was cured by the excision of the fatty pad alone the knowledge that the cartilage was normal roentgenologically giving us confidence in leaving the cartilage in place.

Roentgenological errors occurred in 5 cases. In 2 very small anterior tears were found at operation, though the arthrograph was regarded as normal. In 1 later case, a posterior third tear of a meniscus (lateral) was found. In the remaining 2 cases, tears were diagnosed and at operation nothing but a hypertrophic fatty pad was found. These 2 cases again occurred early in the series when our technique and experience were not developed. In the later cases, our accuracy of roentgenological diagnosis became almost complete.

Every surgeon removing a series of cartilages will admit to some degree of inaccuracy of diagnosis. In our case, this was 8 per cent when unassisted by arthrography. Some of these cases made a clinical recovery which may be accounted for by a hypermobile cartilage, or some other unappreciated factor. It is quite clear that if surgery were limited to roentgenologically positive cases, one hundred per cent accuracy could be obtained but, owing to an occasional failure of the method to show a small tear or a hypertrophic fatty pad, this is not possible. After experience of arthrography we increased the accuracy of diagnosis so that in the 49 cases in which operation was done, only 2 normal cartilages were removed, and both errors would have been avoided if the roentgenograms had been believed, while in the last 39 cases, 100 per cent accuracy has been achieved.

Interesting points raised by arthrography have been

1. The ability to diagnose an early doubtful lesion without waiting for a confirmatory recurrence of trouble, so often recommended as the best procedure. We believe that where a definite "bucket handle" lesion or posterior third tear is shown immediate removal of the

cartilage is justifiable, and thus completes patient's treatment in one stay in the hospital.

2. The frequency with which tears are present in association with cysts of the lateral cartilage has been well shown by the method.

3. A surgeon is given confidence to leave a cartilage in position when exploring a knee for a doubtful lesion, if he discovers a hypertrophic fatty pad which may reasonably be responsible for the symptoms.

4. The increased accuracy of diagnosis of lesions of the fatty pad when the cartilage can be proved normal.

It is, we think, safe to say that air arthrography is a simple procedure devoid of risk, when correctly carried out and that it is a valuable ancillary method of investigation increasing the accuracy of preoperative diagnosis very considerably and capable of raising it to one hundred per cent correct. Practiced as a routine it provided that background of experience in the method, so necessary in the interpretation of difficult cases. It is of particular value in (1) cases in which no adequate history is available (2) cases in which the clinical findings are inconclusive, both as to site of the lesion or its actual presence (3) cases in which a double lesion is suspected either a double tear or a cyst and tear (4) cases in which ligamentous laxity might account for the symptoms, and it is required to prove or disprove associated cartilage damage.

SUMMARY

1. A new technique for air arthrography of the knee is described.
2. The appearances of the normal lateral and medial cartilages are described.
3. The findings in cases of abnormal cartilages are detailed.
4. A summary of the results in 75 cases is given with the clinical conclusions.
5. The accuracy of preoperative diagnosis is considerably increased, and 100 per cent accuracy can be achieved if only roentgenologically positive cases are submitted to operation. As we believe the method incapable of demonstrating lesions other than tears and damage to condylar cartilage a few roentgenologically negative cases must be submitted to operation to introduce a possibility of error

TRAUMATIZED MUSCLE TISSUE AS A FACTOR IN THE PRODUCTION OF SHOCK

EDWARD C. MASON M.D. Ph.D., and D. L. RICHARDSON M.S., M.D.,
Oklahoma City Oklahoma

THE physiological and the pharmacological action of extracts of fresh tissue and the products of tissue decomposition has been studied for over half a century, but the part that these extracts play in shock resulting from trauma is still the object of much controversy. The conflict of opinion concerns the possibility of a systemic reaction resulting from toxic substances liberated at the site of injury.

Those supporting the theory that shock resulting from traumatized tissue is due solely to the local loss of fluid have denied the possible absorption from injured tissue (6, 8, 17, 18, 19, 20, 21). However we now have sufficient evidence to prove that absorption from traumatized areas does occur (5, 7, 15, 16). Also the sequence of events which occurs in the 'crush syndrome' demonstrates the absorption from crushed muscle tissue.

Granting that absorption from traumatized tissue does occur, are the products of tissue disintegration sufficiently toxic to contribute to the production of shock? The confusion which has resulted from the numerous investigations of this problem is apparently due to the failure to distinguish the difference in the action of the three types of tissue extract: (1) fresh tissue extract, (2) autolyzed tissue extract, and (3) tissue extracts containing bacterial metabolites. In our experimental study we have determined blood pressure response to the use of the three types of tissue extracts.

All the records in these experiments were obtained from dogs varying in weight from 10 to 20 kilograms. They were anesthetized with sodium pentobarbital (nembutal) approximately .03 gram per kilogram body weight, injected intravenously and additional injections were made as necessary to maintain the anesthetic level. Blood pressure records were ob-

tained by cannulating the right carotid artery and connecting the cannula to a mercury manometer by means of rubber tubing. The entire system was filled with sodium citrate solution. The respiratory movements were recorded by securing a stethograph drum to the chest.

FRESH TISSUE EXTRACT

Muscle tissue was obtained from dogs under nembutal anesthesia, and the tissue was removed from the thigh and gluteal regions. Care was taken to remove only muscle tissue, in so far as it was possible, and ordinary precautions were taken to prevent the introduction of outside contaminating factors. The muscle tissue was immediately cut into smaller pieces and ground in a meat chopper. One volume of physiological saline solution was added to one volume of the ground muscle tissue; the mixture was put into an Erlenmeyer flask, stoppered, and thoroughly mixed. The muscle-saline preparation then was kept at icebox temperature, approximately 5 degrees centigrade; subsequently it was filtered through several thicknesses of gauze and the filtrate was used for intravenous injections.

Figure 1 is a record of the result obtained from the injection of the saline extract of fresh muscle tissue. It will be observed that the intravenous injection of 1, 2, 4, and 8 cubic centimeters of such extract had little if any effect on the blood pressure. This result may be duplicated repeatedly provided the muscle extract is prepared so as to contain a minimum of fat and particulate matter, and the injections are given in graduated doses. These precautions will prevent the formation of emboli and thrombi (9).

AUTOLYZED TISSUE EXTRACT

The subject of tissue autolysis received renewed interest some years ago when it was demonstrated that a small piece of sectioned

From the Department of Physiology, The University of Oklahoma, School of Medicine.

Fig. 2

liver tissue free within the abdomen would cause death in 15 to 18 hours with the classical symptoms of shock, including hemoconcentration (2, 4, 10-14). Since that time numerous investigators have studied the subject and more recently a comprehensive study of "Tissue Autolysis and Shock" (1) has appeared.

Figure 2 is presented to demonstrate the effect of the intravenous administration of saline extract of muscle tissue which has been subjected to conditions favoring autolysis. The ground muscle with an equal volume of physiological salt solution containing penicillin (more than 30 units per cubic centimeter) was incubated for 17 hours, filtered through gauze and administered. The doses were the same as

Fig. 3

in Figure 1 and the effect was practically identical with that obtained from the fresh muscle extract. We have repeated these observations, allowing the material to incubate as long as 7 days and none of the preparations proved to be markedly toxic. One is forced to conclude that either penicillin prevents the autolysis of muscle tissue or that autolysis of muscle tissue does not produce a toxin sufficiently abundant or active to induce shock.

TISSUE EXTRACTS CONTAINING BACTERIAL METABOLITES

The material for this part of the study was prepared by incubating the ground muscle which had been diluted with an equal volume

Fig. 4

Fig. 4.

of physiological salt solution no antiseptic was added. Figure 3 shows a record obtained during the administration of 1, 2, 4, and 8 cubic centimeters of the filtrate from a preparation which had been incubated for 17 hours. It will be observed that each injection produced a definite fall in blood pressure followed by a sharp rise, the rise often producing a blood pressure nearly twice that of the original. The blood pressure response is practically identical with that previously reported (12) when we used extracts of liver tissue which had been sectioned and left free within the abdomen for 15 to 18 hours. Comparing the blood pressure response recorded in Figure 2 with that recorded in Figure 3, one is impressed with the marked difference; the preparations used were incubated the same length of time and were identical except that penicillin was added to the former before incubating.

The following experiment was undertaken with the desire to determine the concentrations of penicillin necessary to prevent the formation of the toxic material which resulted from incubation. Graduated amounts of penicillin were added to the contents of 10 Erlenmeyer flasks, each containing 50 grams of ground muscle and 50 cubic centimeters of physiological solution. The preparations were thoroughly mixed by shaking and then incubated for 48 hours. Table I is a record of (1)

the amount of penicillin used, (2) the presence or absence of gas and odor, and (3) the blood pressure response to the injection of 4 cubic centimeters of the filtrate obtained from the contents of each flask.

TABLE I

Flask	Units penicillin		Gas and odor	Blood pressure drop to 4 c.c. injection
	Total	Per		
	50,000	500	Neither	None
	5,000	50	Neither	None
3	500	5	Neither	None
4	650	65	Neither	None
5	25	2	Neither	None
6	1,550	6	Neither	None
7	780	8	Gas	26 mm.
8	390	4	Gas	6 mm.
9	95		Gas and odor	54 mm. (with sec. rise)
10	97		Gas and odor	Not injected

Desiring to test the effectiveness of sulfadiazine, we added an excessive amount to the muscle-saline mixture, 1 gram to 250 cubic centimeters, mixed thoroughly and incubated for 17 hours. Figure 4 demonstrates the effect of the intravenous injection of 1, 2, 4, and 8 cubic centimeters of the filtrate. It will be noted that the amount of blood pressure reduction resulting from each injection was es-

Fig. 5

scially the same, approximately one half of the original pressure regardless of the amount of injected material. No secondary rise in blood pressure occurred as observed in Figure 3

BURNED TISSUE EXTRACT

A weighed amount of ground dog muscle was placed in a dry clean (grease free) frying pan and heated. The degree of heat and the length of time were varied depending upon the degree of burning desired. All degrees of burning were studied from cooking until the pink color disappeared from the center of the mass to charring the entire muscle tissue. The burned tissue was placed in an Erlenmeyer flask and treated with a volume of physiological salt solution equal to the original muscle mass. It was then shaken thoroughly and kept at icebox temperature until used, at which time it was filtered and the filtrate injected intravenously.

The intravenous administration of the filtrate obtained from the saline extract of burned muscle tissue usually produced little if any change in blood pressure. Figure 5 is a record obtained during the injection of 2, 4, 8 and 16 cubic centimeters of such a filtrate. The dose given is double that which was used in the previous records and the response is not marked.

CONCLUSIONS

1. Extracts of fresh muscle tissue, administered intravenously produced little if any change in blood pressure.
2. The use of the filtrate obtained from ground muscle incubated with penicillin also produced little change in blood pressure.
3. The filtrate of muscle tissue incubated with sulfadiazine produced a marked lowering of blood pressure, the drop being equal to approximately one-half of the original pressure.
4. Extracts of muscle tissue incubated without the presence of any antiseptic produced a fall in blood pressure followed by a secondary rise. The increased blood pressure was often double the original pressure.
5. The blood pressure response to incubated muscle tissue, without an antiseptic, is practically identical with that we have previously reported when using extracts of liver tissue sectioned and left free within the abdomen.
6. Administration of the saline solution extract of burned fresh muscle tissue produced little if any change in blood pressure.

AN IMPROVED PERMANENT COLOSTOMY

B. K. RANK, and JULIAN SMITH Jr., Melbourne Australia

THE prospective owner of a permanent colostomy must view his future with awe. Nevertheless the early repugnance with which patients regard their disability is usually replaced by a sense of the inevitable. The possible cure of a foul disease seems to lend them support to maintain a tolerable existence.

Apart from the infrequent surgical complications of stenosis and prolapse however expert may have been the performance of the operation, there remains the imperfection that the colostomy in regard to fluid loss and gas is uncontrollable, even artificially. Rubber bags, obturators of various kinds, complicated, and therefore cumbersome, colostomy cups have all had their day and have been found wanting in many ways. The mucous membrane of the colon will not withstand plugging for any length of time and so far as we are aware any attempt to control the efflux of feces in this way has failed. It has been established beyond question that the best fashioned colostomy is a severe domestic and social embarrassment.

It occurred to one of us (JOS) while observing the other (B.K.R.) constructing buried inverted skin tubes for a cineplastic forearm amputation, that a similar type of skin tube might be made as the terminal segment of a colostomy with some prospect of the successful use of a mechanical plug.

In adapting this suggestion it was ultimately decided that the appropriate surgical procedure would best be designed and executed in two stages. This for two reasons.

1 To avoid stricture formation. Areas in relation to the anastomosis of skin tube with bowel cannot be left prone to secondary intention healing and scar formation. This is more easily achieved if the skin tube is made and healed as a primary procedure before any attempt at mucocutaneous anastomosis. Only in this way can new suture lines meeting in divers planes and directions be avoided. Such

are always vulnerable points, even in favorable circumstances, but in association with fecal contamination rarely could effective primary healing be expected.

2 To avoid increase of operation risk. Patients mainly of the upper age group, after a preneobdominal operation for excision of the rectum are generally unfit to withstand the extra time of a tedious plastic operation. Moreover patients in low ebb of vitality are poor subjects in which to embark on plastic procedures which at least require a healthy peripheral circulation.

Using variations of common principles our object was successfully accomplished by one of us (B.K.R.) in 3 cases with an evolution of method and success. Without expounding details which were tried and the difficulties encountered the method used in the third case will now be described as a prototype operation in relation to Figure 1.

STAGE I

Construction of a buried inverted skin tube. A rectangle of skin $ABA'B'$, approximately 2 by 4 inches is designed (Fig. 1a) on the lower left quadrant of the abdomen. The center of its upper and long side is at a point lateral to the rectal sheath where the bowel is to leave the abdomen. This skin area will line the tube. The ends only of the rectangle are raised as two separate flaps of skin and fat (Fig. 1b) each flap containing slightly less than one third of the rectangular area. When each of these flaps is turned back on its attached base the free ends are sutured together to make a skin lined tube (Fig. 1c). Silk is used for this suturing. Separate inverted end-on mattress sutures are used at either end of the tube, and a continuous subcuticular mattress stitch along its length. The latter is anchored at either end to the single stitches and left long for identification purposes.

There now remains a raw surface corresponding to the area of the original rectangle

SURGERY GYNECOLOGY AND OBSTETRICS

marked out. This surface is covered by a flap of appropriate dimensions transposed from the region CDEF on an oblique base CD (Fig 1d). This is a "safe" flap. When transposed to the raw area (Fig 1e) its center portion will overlap the outside of the skin tube. Its whole free margin is sutured to the defect. This means that the central parts of its long margins are sutured to the free skin circumference at each end of the skin tube. Interrupted stitches of fine silk are used for this purpose.

This completes the skin tube but leaves a secondary defect in the left loin. In some subjects with a loose abdominal wall, after wide lateral undermining it is possible to close the secondary defect by direct suture (Fig 1f, A). In others it is better closed by a large rotation advancement flap (Fig 1f, B). This flap serves a twofold purpose in distributing tension over a long suture line and transferring maximum tension to a remote region of relatively no importance.

STAGE 2

Anastomosis of the bowel end to the skin tube.

Skin incisions WXYZ are made (Fig 1g) including a ring incision around the proximal circumference of the skin tube. Turning back the flaps WXY and WXZ (Fig 1h) the abdominal is now opened as through a muscle splitting incision. The free end of the bowel tied with a tape during the main abdominal operation is delivered through this wound leaving sufficient length for subcutaneous anastomosis to the skin tube. After trimming the bowel end is anastomosed to the skin lining of the tube (Fig 1i) with many interrupted catgut stitches including some inverted mattress stitches. The skin wound is now closed so that the flaps WXY and WXZ now lie anterior to the bowel, the line XY and the line XZ are outside the line of mucocutaneous anastomosis and X meets X (Fig 1j). The final scars of surface suture lines are either as marked in Figure 1k or 1l, according to the manner in which the secondary defect was closed in Stage 1.

SUMMARIES OF CASE REPORTS

CASE 1 (Lt. Col. Smith's patient.) Bdr J H., aged 35 years, had a fungating carcinoma of the rectum

with papillomatosis. His operation program was as follows:

Operation 1 was performed May 15, 1944 under local anesthetic. A buried inverted skin tube was made (Stage 1). Primary healing followed.

Operation 2 was performed June 16, 1944, under general anesthesia. Excision of rectum and lower sigmoid were done by the combined approach (Lt. Col. Smith and Major Ackland). Bowel skin tube anastomosis was made (Stage 2). The mistake was made of not joining the iliac wound to the marginal incision around the skin tube opening. The bowel anastomosis was not buried, and there was a bridge of abdominal skin beneath the exposed bowel. At this stage there was no colostomy opening other than by the skin tube, but a days later the bowel was opened to function as a colostomy on its exposed portion above the skin tube anastomosis. After this, the mucocutaneous anastomosis became detached.

Operation 3 was performed August 9, 1944 under general anesthesia. Reanastomosis of bowel to skin tube was done. This time the anastomosis was buried by raising the bridge of skin between the iliac wound and skin tube and by laying the bowel beneath it. This was distal to the now functioning colostomy. This anastomosis remained clean and healed.

Operation 4 was performed August 21, 1944 under general anesthetic. Closure of colostomy and barial of exposed bowel were done. A large Eastlander type skin flap was used. There was a good deal of pain and distention following this operation but after a purgative, the bowel discharged freely through the skin tube. Three small fistules then developed in the suture line proximal to the skin tube. Two of these healed rapidly, and spontaneously the third eventually closed.

On November 10, 1944, all was well healed, and he commenced to plug intermittently the skin tube with dental rolls. An acrylic plug was later supplied him.

On July 10, 1945, when last reviewed, the skin tube colostomy was clean and easily manageable. His bowel opens in the morning after which he plugs the skin tube with an acrylic plug retained by a belt. He complains of occasional wind and distention. A finger could be easily passed up the skin tube into the bowel without any suggestion of stenosis.

Photographs of this patient are shown in Figure 1k.

CASE 2 (Lt. Col. Remou's patient.) Cpl. C.F.N. aged 41 years, had an ulcerating carcinoma of the rectum. His operative program was carried out as follows:

Operation 1 was done August 8, 1945, under local anesthesia. Buried inverted skin tube was made (Stage 1). Primary healing followed.

Operation 2 was performed August 23, 1945 under general anesthesia. Combined abdominoperineal excision of the rectum (Lt. Col. Remou and Major

incisions made for anastomosis of bowel end to skin tube. h. Flaps turned back from these incisions. i. Bowel end anastomosed to skin lining of the tube. j. Closure of wounds. k, l. Final scars of suture lines, according to method of closing the secondary defect.

Fig. 2. Method of plugging. a, Case 1. b, Case 2. c, Case 3.

Blackay) was performed. Buried anastomosis was made of bowel to skin tube. Proximal to this the bowel was left uncovered by skin and was opened.

Operation 3 was done, September 24, 1945 under local anesthesia. Closure of a fistula was made at site of partial breakdown of mucocutaneous anastomosis. This too subsequently broke down. It was difficult to prevent feces getting into the bowel distal to the colostomy opening despite many types of dressing and packing.

Operation 4 was performed October 13, 1945 under local anesthesia. Transverse colostomy.

Operation 5 was performed November 3, 1945 under local anesthesia. Closure of recurrent fecal fistula in mucocutaneous anastomosis. Closure of distal colostomy. After this all wounds remained healed.

Operation 6 was performed November 21, 1945 under general anesthesia. Closure of transverse colostomy was done. On December 3, 1945 he started to use a plug in the skin tube.

On July 1946 when last reviewed, colostomy was clean and easy to manage. He is in the habit of inserting a plug after his bowel action in the morning. He has good bowel habit and control and gets sensation of fullness when the plug is in situ with the bowel full. He is using a plug made with a wind vent as in Figure 3.

This case is illustrated in Figure 2b.

CASE 3. (Major Blackay patient) Pte J. P. H. aged 54 years, had a carcinoma of the rectum. His operative program was as follows:

Operation 1 was performed September 26, 1945 under general anesthesia. Laparotomy and transverse colostomy were carried out. Construction of buried skin tube was made (Stage 1). Four days later the transverse colostomy was opened. The main operation was postponed for some time because of a cardiac condition indicating special treatment.

Operation 2 was performed December 3, 1945 under spinal and gas anesthesia. Abdominoperineal excision of rectum was done (Lt. Col. Renou and

Fig. 3 Acrylic plug with wind vent. Model as used in Case 2

Major Mackay) Distal free end of sigmoid anastomosed to proximal end of skin tube and buried subcutaneously as described in stage 2 of prototype operation. This healed *per primam*.

Operation 3 was January 31, 1946 under local anesthesia. Closure of transverse colostomy extra perineal, was done.

On February 1, 1946 the skin tube colostomy commenced to function and has continued satisfactorily since. An acrylic plug was made and fitted which at first caused some difficulty because of the persistently fluid nature of his feces.

On June 1, 1946 patient was fitted with a new type of plug which he was managing well.

This patient (Fig. 3c) subsequently developed recurrence of growth in the perineal wound. He became bedridden and though he abandoned use of the plug the skin tube colostomy remained clean and functioned well, despite repeated bouts of diarrhea.

In Cases 1 and 2 we failed to achieve primary healing in the anastomosis of bowel to the skin tube. There was breakdown with fecal fistulas at the junction line. In the first case it is still to be wondered that spontaneous healing—though delayed—did occur. In the second case the fistulas were only closed after

Fig. 4 External appearance of the skin tube colostomy of over 2 years standing. The photograph shows the skin in good condition. There has never been any skin irritation or breakdown.

a secondary transverse colostomy was done to break the fecal flow. In the third case where preliminary colostomy had been done so that the original anastomosis at the end of the major operation for rectal excision was done on a defunctioned bowel the optimum of primary healing was obtained.

On this experience it is our considered opinion that the anastomosing procedure is best attempted only on a defunctioned bowel despite the disadvantage of the extra stages it involves. The best initial procedure is a limited abdominal exploration with transverse colostomy. It is not our purpose at this juncture to argue whether formal exploration should be dispensed with or not, but rather to state that a transverse colostomy is the essential preliminary to an efficient mucocutaneous anastomosis later.

In relation to an elective operation for rectal excision as for cancer we consider the operative program to achieve a skin tube colostomy in the safest and most satisfactory way should be in three stages.

Operation 1 (a) laparotomy, (b) construction of buried skin tube (Stage 1) (c) transverse colostomy.

Operation 2 (a) abdominoperineal excision of rectum (b) buried anastomosis of terminal bowel end to skin tube (Stage 2)

Operation 3 closure of transverse colostomy

THE PLUG

The main purpose of the operation implies the use of an efficient plug to render the colostomy controllable. At first dental rolls of packed wool were used. These were too easily and rapidly forced out and it seemed that some retention arrangement was necessary. Various types of rigid acrylic plug and retention arrangements have been made and tried including one to allow wind escape (Fig. 3). The patient in Case 2 uses this effectively, but finds it difficult to keep clean. Some soft material (such as polyvinyl) or the use of an inflatable cuff with some attempt to shape the skin tube may be the indication.

Many more cases require to be done before any definite conclusions can be made of the value of such a colostomy including further work and elaboration on the best medium, means, and routine of plugging the skin tube.

We regard this only as a preliminary report warranted by the establishment of a new prin-

ciple in colostomy which we have demonstrated as a practical proposition. We do not believe that the principle should be applied to all cases of colostomy. It appears desirable in such a patient as our first case, a man 35 years old with the prospect of many years of life before him but condemned to an artificial anus. Our longest standing case of over 2 years has shown that the skin tolerates both feces and plugging with no untoward effect (Fig. 4). When the colostomy is plugged a sensation of local fullness in the region is experienced when the bowel is full. The skin tube colostomy can be easily kept clean and is altogether a more controllable and more manageable proposition than the standard types of colostomy.

With appropriate teamwork the necessary procedures can be carried out without added risk to the subject and with no undue upset of the main plan and procedures necessary to operation.

AN EVALUATION OF ABDOMINAL WOUND CLOSURE

Steel Wire Layer Closure Compared with Catgut-Silk Layer Closure, Early and Late Results

H. M. WILEY, M.D. and EVERETT D. SUGARBAKER, M.D., Columbia, Missouri

CONSIDERABLE controversy still exists among surgeons in the choice of suture material and the method of closure of abdominal wounds. We wish to present a method of abdominal wound closure which, though not new, has so decreased our early and late wound complications as to bear emphasis.

Two hundred twenty celiotomy wounds were studied, 110 of these were closed with a catgut-silk combination, and 110 were closed with a steel wire-silk combination.

The patients studied present a rather severe test of wound closure. All belong to an economically indigent group derived from rural areas. One hundred and fifty nine patients had some type of abdominal cancer. The average age of the entire group was 58 years. In this hospital approximately 45 per cent of the patients upon whom major surgery is performed have a total serum protein on admission below 6.3 grams per cent and about 90 per cent show a decline in their serum protein postoperatively despite vigorous protein therapy (10). A high incidence of marked weight loss (9) and frequently a moderate to severe anemia on admission are common findings. Because of these adverse factors it is mandatory that every effort possible be made to prevent the development of postoperative complications. As has lately been re-emphasized (8) a high degree of control of all possible factors in surgery on such patients is essential if success is to be attained with regularity. The use of steel wire in closing abdominal wounds as described later has provided an additional safety factor. A careful follow up of all patients makes it possible not only to observe the early but the late wound complications.

From the Department of Surgery, Ellis Fischel State Cancer Hospital.
Dr. Wiley is a trainee, National Cancer Institute, and Resident Surgeon.

The suture materials used in this study have included catgut, silk, cotton, and steel wire. Large has shown a decreasing tolerance to suture material in the following order: fine stainless steel wire, cotton, silk, plastigut, nylon, and catgut.

The method of closure for those patients in whom catgut and silk were used was as follows: The peritoneum was closed with a continuous No. 1 chromic catgut stitch. The other layers—fascia, subcutaneous tissue and skin—were approximated with interrupted silk sutures. Approximately one-third of these wounds (35 per cent) were reinforced with silkworm gut stay sutures through the skin, subcutaneous tissue, rectus muscle, and anterior rectus sheath.

The method of closure in the group in which steel wire and silk were employed is essentially the same as that used by Louis Sneed and described by Jones. We have modified it inasmuch as we use interrupted fine silk or cotton to close the subcutaneous tissue and interrupted silk or cotton to approximate the skin. The wire used is an alloy steel wire (No. 28 or 30). We have noted that if a finer grade than No. 30 is used it has a tendency to cut the tissues. At present we prefer the heavier grade No. 28. The alloy steel wire stitch goes through both layers of the rectus sheath, the intervening muscle, and the peritoneum. The stitch is then brought out through all of these layers on the opposite side of the wound and a second loop is taken to approximate the anterior fascial layer of the rectus sheath (Fig. 1). Recently we have noted that at times precise apposition of the peritoneum did not always result with this technique. Accordingly we now incorporate a loop through the peritoneum and the rest of the stitch is taken as described (Fig. 2). Before placing the anterior fascial loop the stitch

Figs. 1 and 2 Method of closing abdominal wound.

is drawn snug apposing the peritoneum. Deep bites of tissue are taken (1.5 to 2.5 cm.) on each side of the wound to add strength to the closure during the initial postoperative period and to provide more cushioning, and therefore less strangulation of the tissues. The stitch is drawn snug and a double square knot is then tied about 1 centimeter above the anterior fascial sheath. Approximation of the wound is all that is needed and when the suture is released it lies loosely in the tissues. A tightly drawn suture will cause wound edema or even ischemic necrosis. The later complication has not been observed at this hospital. After they are tied the wires are cut flush with a hemostat placed just above the knot. The hemostat is then rotated so that the cut ends of the wire are turned downward. This is particularly important in individuals with little subcutaneous fat, otherwise the sharp ends may impinge on the under surface of the skin and cause pain. This method of wound closure does not eliminate the necessity for careful asepsis and hemostasis. We believe it promotes gentleness in the handling of tissues as one stitch approximates the peritoneum rectus sheath and muscle.

The complications encountered with these two methods of abdominal wound closure consisted of 37 (3.36 per cent) in the catgut-silk group and 8 (0.07 per cent) in the wire-silk group. Five minor wound infections occurred in the catgut-silk group and 6 in the wire-silk group. Four major infections occurred in the former group and none in the latter group. Of the wounds which became infected in the catgut-silk group 3 were classified as potentially contaminated at the time of operation. In the wire-silk group 1 was classified as potentially contaminated at operation.

Dehiscences are divided into major and minor the former term being used when the wound separated to the peritoneum from within or to the skin from within the latter when only skin and subcutaneous tissue separated. There were 2 minor and 5 major dehiscences in the catgut-silk group, and none in the wire-silk group.

The term eventration is used only when there was actual protrusion of abdominal viscera through the wound. The incidence of eventrations in the 158 cancer patients in both groups was 1.8 per cent. This is in keeping with the findings of others. Glenn and Moore reported an incidence of eventration of 1.39 per cent in patients with malignant disease and of 0.51 per cent in patients without malignant disease. The 3 eventrations occurring in this study were in the catgut-silk group and as is seen in Table I they are all in patients with cancer. One of the patients in whom evisceration occurred subsequently died in the hospital of peritonitis. An added initial strain was placed on the wound in most of the patients in the steel-wire group inasmuch as they were gotten up on the first or second postoperative day. However in spite of this there were no dehiscences or eventrations. In the nonmalignant conditions also fewer complications occurred in the steel-wire-silk group.

A study of the late results shows 12 postoperative incisional hernias in the catgut-silk group and none in the wire-silk group. In the catgut-silk group there were 36 and in the wire-silk group 35 patients who had cancer of the rectum or the lower sigmoid, requiring permanent colostomies. In the catgut-silk group the permanent colostomy was customarily brought out through an accessory muscle splitting incision in the left lower quadrant.

In the wire-silk group the colostomy was brought out through the original left rectus muscle splitting incision. In the 36 patients in the catgut-silk group 11 developed hernias about the colostomy. In the 35 patients in the wire silk group 3 developed hernias about the colostomy. Two of these were loop colostomies. Because of the subsequent atrophy of the defunctionated distal limb a disproportion not infrequently develops between the wound opening as originally made and the bowel. Accordingly it is not uncommon to find late herniation about loop colostomies regardless of the type of wound closure. At the present time almost all colostomies both permanent and temporary are brought out through the rectus muscle splitting abdominal incision. The wounds have healed per primam, and in temporary colostomies the closures have been accomplished without difficulty or wound weakness.

One painful incision occurred in each group. The one in the catgut-silk group was not relieved by excision of the painful scar and the one in the wire-silk group was not relieved by removal of the wire stitches. Both patients were considered to be hyperesthetic individuals in other respects.

There were 4 instances of sinus tract formation in the catgut-silk group as compared to 1 in the wire silk group. Jones also observed a low incidence of sinus tract formation following the use of buried alloy-steel wire.

In the presence of infection or gross soiling we feel that steel wire employed in the manner described is the suture material of choice. Since the above investigation was made we have had 1 patient who had a colostomy and developed postoperative intestinal obstruction. At the time of operation after release of the obstruction there was inadvertent spilling of fecal material from the colostomy into the abdominal wound. The wound was closed with steel wire as described previously. On the fourth postoperative day because of infection throughout the entire length of the subcutaneous layer down to the anterior layer of the rectus sheath the wound had to be opened superficially and the steel wire sutures were exposed in the base of the wound. In spite of repeated contamination from the colo-

TABLE I.—EARLY AND LATE ABDOMINAL WOUND COMPLICATIONS IN MALIGNANT CONDITIONS

stomy the wound rapidly healed with the application of wet dressings and with daily irrigations. The granulation tissue quickly covered the steel wires without the development of sinus tracts or incisional hernia.

DISCUSSION

A through-and-through closure (stay suture) of some nonabsorbable suture material has been generally accepted as the best method for closure of disrupted wounds.^(1, 2, 7) The value of careful approximation of fascial layers has been stressed by Howes and Norris.⁸ The technique described here employing stainless steel wire has the combined advantages of a layer closure because of the small loops which appose the peritoneum and fascia, and of a stay suture because of the through and through loop with its deep bites of tissue. This method of closure eliminates the need for conventional stay sutures.

It has frequently been noted that the interstices in multifilament suture material act as niduses for the growth of bacteria in contaminated or questionably clean wounds and in the presence of infection may result in sinus tract formation. This possibility is eliminated when steel wire is used.

We believe that the greater success of steel wire abdominal wound closure as it has been described can be attributed to the following factors.

1. The greater tensile strength produces a stronger wound in the immediate postoperative period before wound repair has occurred.

2 Less trauma is necessary and tissue strangulation may more easily be avoided in placing sutures in such a manner than is possible with the usual types of layer closure.

3 This combined with the fact that there is less tissue reaction to the alloy steel, promotes increased resistance to infection and more rapid wound healing.

SUMMARY AND CONCLUSIONS

1 A comparison between 110 abdominal wounds closed with catgut-silk is made with a similar number closed with alloy steel wire.

2 The overall incidence of wound complications in the catgut-silk group was 37 (33.6 per cent) and in the steel wire group 8 (0.07 per cent).

3 Alloy steel wire was well tolerated by the tissues. It can be used in the presence of infection with little fear of sinus tract formation.

4 Dehiscences or eversions occurred in 10 wounds (9 per cent) in the catgut-silk group. No such accident occurred in the steel wire group.

5 Postoperative incisional hernias were

reduced from 12 (11 per cent) in the catgut silk group to none in the steel wire group.

6 We believe that the method described for using alloy steel wire produces less trauma, results in maximum tensile strength during the early postoperative period when it is most needed and combines the advantages of a layer closure with the advantages of a stay suture closure.

7 The use of alloy steel wire has provided an added safety factor in the surgical management of the poor risk patient.

INTESTINAL LIPODYSTROPHY (WHIPPLE'S DISEASE)

Preliminary Report of Three Cases in an Early Stage of the Disease
J deJ PEMBERTON M.D., F.A.C.S., MANDRED W COMFORT M.D EDWIN FAIR M.D.,
and JERRY ZASLOW M.D., Rochester Minnesota

SINCE Whipple first described a case of "intestinal lipodystrophy" in 1907, 13 additional cases have been reported in the literature (1-3 5 6 9-14). Recently, 3 patients who we believe had the disease in an early stage came under our care. The condition of all was suspected on the basis of the gross observations made at operation, and the suspicion was confirmed by the results of biopsy. In addition to the fact that these 3 patients presumably had a rarely described disease, they are of interest because the condition was diagnosed relatively early and because an opportunity became available for study of the disease as it progresses.

REPORT OF CASES

CASE 1: A man 65 years old was admitted to the Mayo Clinic on December 26, 1945 with a history of change in bowel habits of 3 months duration and pain of 3 months duration in the lower part of the abdomen. Otherwise the medical history revealed several joints for a period of 1 week when the patient was 16 years old. Three months before admission of the patient he had begun to have two to four small, hard, lumpy stools daily, in contrast to one normal stool daily previous to that time. One month later an intermittent, cramplike type of pain in the lower part of the abdomen had developed. These symptoms had continued unremittingly. Four days before his admission the patient had experienced rather severe, persistent low backache. At no time had there been any symptoms referable to the upper part of the gastrointestinal tract. Results of a general systemic inquiry were negative except for the information that about 30 pounds (about 14 kgm.) had been lost during the preceding year.

Physical examination revealed only an indefinite nontender mass in the upper and middle parts of the abdomen. The essential laboratory observations are summarized in Table I. Results of roentgenologic examination of the stomach, small intestine and colon were negative.

Because of the presence of an abdominal mass and because loss of weight appeared to be progressive, From the Divisions of Surgery and of Medicine Mayo Clinic and the Division of Surgery Mayo Foundation.

the patient underwent operation on January 4, 1946. The tissues of the mesentery of the small intestine were found to be greatly swollen and thickened. They presented a dirty creamy color suggestive of that of dilated lacteal vessels. There were no firm tumors. On palpation the mass in the abdomen felt leathery. The tissues most involved were those at the attachment of the mesentery to the posterior abdominal wall. There was some extension of the process into the mesentery toward the small bowel. The wall of the small bowel was normal. The pancreas was normal to inspection and palpation. There was no evidence that any tumor was compressing the thoracic duct. Results of further exploration of the abdomen were negative. A specimen of tissue near the base of the mesentery and another specimen from a more distal portion of mesentery were taken for histopathologic study.

Sections of the tissues in question proved to contain intracellular and extracellular fat, numerous mononuclear foam cells marked necrosis of fat with a cellular infiltration consisting mainly of lymphocytes but also including occasional polymorphonuclear and eosinophilic cells. In several places fibrosis of varying degree was demonstrated. There was only an occasional foreign-body giant cell to be seen (Fig. 1 a).

The postoperative course of this patient was uneventful. As a result of the observations made at operation additional studies relating to digestion and absorption were carried out (Table I). A special diet in which 101.6 grams of fat and 117.5 grams of protein were to be ingested daily was prescribed. The average daily content of fats and nitrogen in the feces was within normal limits. The blood fats were studied. In general the values for blood fats were found to be low normal or subnormal. The values for blood calcium, phosphorus and serum protein were normal or approximately so. The basal metabolic rate and the values for gastric acids were reported as normal. The patient continued to have mild leucocytosis and to lose weight in spite of the fact that he was eating food that provided 2,400 calories daily. Results of the Extol and Rose glucose tolerance test and vitamin A tolerance tests were normal.

During the patient's postoperative course in the hospital a few small discrete lymph nodes were felt in each groin and in the left axilla. However, specimens for biopsy were not taken from any of these three locations. It was decided to watch for any further enlargement.

SURGERY GYNECOLOGY AND OBSTETRICS

The patient received roentgenologic treatments on four successive days. They were administered over the abdomen. He was instructed to take one to two tablets of a choleretic agent (ketochol, a form of bile salts) after each meal. This treatment was based on the apparent success achieved with roentgen rays in Boeck's case and with bile salts therapy in Pearce's case.

CASE 2 A woman, 63 years old, was admitted to the clinic on February 8, 1946 complaining of an abdominal mass that had been found by her referring physician during a physical examination. The history revealed that the patient had had smallpox in 1911 and pyelitis in 1935 and 1943. A stone in the left ureter had been found in 1943. Surgical treatment carried out previously included appendectomy in 1916, hysterectomy and oophorectomy for cancer of the uterus in 1917 and cholecystectomy for gall stones in 1935. The patient had had hypertension subsequent to 1935; the blood pressure at systole usually was found to be around 200 millimeters of mercury.

In August, 1945 the patient had had an attack of distress in the upper part of the abdomen. The pain

had extended to the shoulder blades and was relieved by vomiting. In December 1945 she had had a similar attack and had applied heat locally for relief. She had burned her abdomen, and in the course of treatment her physician had felt an abdominal mass. A careful systemic inquiry revealed that she had had six episodes of diarrhea, each lasting a week, in the year prior to her admission to the clinic. At these times she had passed four to eight stools during the first 8 hours after breakfast. Sometimes nausea and vomiting, but not pain, had occurred. The diarrhetic stool had consisted mainly of undigested food, and occasionally of mucus and frothy material. The patient believed that her stools had become bulkier during the period of the year prior to the time when we saw her.

On physical examination the patient was found to have a systolic blood pressure of 110 and a diastolic pressure of 80 expressed in millimeters of mercury. The pulse rate and temperature were normal. Abdominal examination revealed an ill-defined non-umbilical mass which was situated at the level of the

The essential laboratory observations are included

PEMBERTON ET AL. INTESTINAL LIPODYSTROPHY

in Table II. Results of roentgenograms taken of the colon and of the thorax were negative. The sedimentation rate of the blood was 16 millimeters in 1 hour (Westergren method).

On February 14, 1946 the patient was operated on by Dr. D. O. Ferris. In the surgical report it was said "The mass was found to be in the mesentery of the small bowel. It arose from the root of the mesentery and at the site was 2 to 3 inches in thickness and looked like fat necrosis. Interestingly the lacteals of the small bowel were all dilated and were two to three times normal size, making definite white streaks across the small bowel. The other organs were reported as being normal. A specimen of tissue was taken for microscopic study (Fig. 1 b). The description of the specimen is exactly that given for the specimen concerned in the preceding case. In both cases the absence of many giant cells and much dilated itself was in a relatively early stage meaning lymph spaces and more fibrosis would have been observed."

The condition of this patient was also studied postoperatively from the standpoint of possible abnormalities in intestinal absorption and in fat metabolism. The observations are summarized in Table II. All the results of laboratory studies were within normal limits. The patient was dismissed after being instructed in the taking of bile salts.

CASE 3. A woman, 58 years old was first admitted to the clinic on December 31, 1928. At that time she was found to have a duodenal ulcer, had severe and mild arthritis of the left shoulder. She was again seen at the clinic on December 11, 1945. She had followed a medical regimen for the ulcer for about 15 years with satisfactory results. Regression of the symptoms of arthritis had occurred and persisted for several years, but pain and aching had been present during the 3 years prior to her last admission. At the time of this admission she complained mainly of a constant ache in the upper part of the abdomen with frequent nausea, flatulence, occasional light colored stools and intolerance to fatty foods. She had not been present, however, the patient had had loose stools described as mucus stools. There had not been any loss of weight.

Physical examination revealed a palpable tumor mass in the epigastrium and left side of the upper part of the abdomen. It was firm, irregular, not very tender and partially fixed. The essential laboratory observations are found in Table III. Results of roentgenologic examinations of the gall bladder, stomach, colon and terminal portion of the ileum were negative, except for the duodenal ulcer.

The patient was operated on by Dr. S. W. Harrington on December 19, 1945. His report was as follows: Upon exploration of the tumor mass in the left upper abdomen it was found to be a diffuse area of thickening at the extreme root of the mesentery immediately over the aorta, beginning in the mesen-

tery of the jejunum at the ligament of Treitz and extending down almost to the pelvis involving most of the root of the mesentery of the small bowel. The area had a light yellow, milky color. The area was about 2 to 3 centimeters in thickness at the largest part. It did not come up to the small bowel. There was an area of normal appearing mesentery at least 2 1/2 to 3 inches from the mesenteric margin of the jejunum.

A perforating duodenal ulcer with moderate obstruction was fixed to the pancreas. The other organs were found to be normal. Partial gastrectomy of the posterior Pólya type was done. A specimen of tissue from the tumor mass was taken for microscopic study (Fig. 1 c). The microscopic appearance was that of inflammatory fat. There were both intracellular fat and extracellular fat. There were both clear foam cells and necrosis. There was infiltration of lymphocytes with occasional polymorphonuclear and eosinophilic cell also fibrosis in several areas. The postoperative course was uneventful. The patient was dismissed from the hospital on the

twenty-second postoperative day and from the clinic on the twenty-fourth postoperative day. She returned to the clinic on June 19, 1946 for a postoperative examination at the end of 6 months. Constant aching over the abdomen had persisted, but there had been no loss of weight. At the time of this last examination she underwent studies of abnormalities in intestinal absorption and digestion of fat. These observations are summarized in Table III. Results of all the laboratory studies were within normal limits. The patient received a course of roentgen therapy over the abdomen on four successive days. She was not given bile salts.

In all 3 cases the studies of pathologic tissue were done by Dr. John R. McDonald.

In the cases of intestinal lipodystrophy reported in the literature the anatomic data are similar enough to indicate that the condition is a definite disease entity. A brief review will be presented of the essential symptoms, physical observations, laboratory data, and ana-

tomic characteristics in the cases thus far reported.

Clinical picture. In the 14 reported cases, 13 patients were men. The mean age was 49 years the majority of patients were in the fifth and sixth decades. Early in the course of the disease postprandial discomfort, indigestion and gaseous distention are noted. Later diarrhea, severe loss of weight, progressive asthenia and general debility are present. In 4 cases the diarrhea was associated with gross blood in the stools. In 2 cases constipation was reported. The diarrhea was often associated with steatorrhea. The symptoms varied in duration from 6 months to 15 years. 9 of the patients had had distress for more than 2 years. In 6 cases there was a history of arthritis.

The physical observations are those associated with general debility. The abdomen often is described as feeling like dough at palpation and the lymph nodes are sometimes palpated as abdominal masses. Four patients had slight icterus, two had purpura and about half had a moderate degree of dependent edema. Inguinal and axillary lymph nodes were palpably enlarged in 2 cases. In the few cases in which the disease has been so studied, results of roentgenologic examination of the gastrointestinal tract were normal.

All patients in these reported cases had moderate anemia, but only 2 had leucocytosis. Six had achlorhydria. Results of urinalysis were normal as were results of studies of blood chemistry. Studies of stools did not disclose ova, parasites, or significant organisms. In 2 cases chemical analysis of the stool was made. In Whipple a case 80 per cent of the dried stool was fat, of this fat, 50 per cent was neutral fat and 30 per cent was fatty acids. In Pearce a case, about 60 per cent of the dried stool was fat, 44 per cent of this was fatty acids, 12 per cent was neutral fat and 3 per cent was unsaponifiable substance. After treatment with bile salts orally the percentage of fat in the stools of Pearce a patient decreased to 25 only fatty acids being present.

Pathologic aspects. The essential pathologic observations are present in the mesenteric portion of the small bowel and its mesentery.

Fig. 1 a, Tissue from the mesentery of the small bowel in Case 1 showing numerous mononuclear foam cells, intracellular and extracellular fat, moderate infiltration of lymphocytes and minimal fibrosis (hematoxylin and eosin, X135) b, tissue from similar situation in Case 2 with ap-

proximately the same changes (hematoxylin and eosin X135) c, tissue from Case 3 with changes similar to those in the other two (hematoxylin and eosin X135)

Grossly the mesentery is thickened yellow and has a rubber consistency. The lymph nodes in the mesentery, and especially those near the root are enlarged firm and on cut section often present a spongy appearance because of dilatation of the lymph sinuses. The lacteal vessels may be dilated enough to be seen grossly. The mucosa of the jejunum and ileum is either normal in appearance or is swollen and flecked with minute deposits of yellowish white lipid. In 3 reported cases there was chylous ascites in 7 cases fibrous pericarditis was present. Microscopic examination of the mesentery reveals marked dilatation of the lymph vessels and the presence of large mononuclear foam cells extracellular as well as intracellular fat deposits, foreign body giant cells lymphocytic infiltration and fibrosis. The mesenteric lymph nodes present a similar picture. In 11 of the 14 cases the small intestine presented similar changes in the stroma of the mucosa and submucosa.

Our first patient presented only loss of weight rapid emaciation and cramps in the lower part of the abdomen. The diagnosis was suspected on the basis of the characteristic appearance of the mesentery of the small bowel at operation and was confirmed by microscopic examination of specimens taken for biopsy. Although this patient did not have steatorrhea and the fat content of the stool and absorption of vitamin A were normal the values for blood fats were low normal or subnormal at all times. Laboratory data con-

cerning the second and third patients were entirely normal. Interestingly enough all 3 patients were operated on because of the finding on physical examination of an indeterminate mass and relatively minor systemic or local symptoms. None had the steatorrhea or the well developed picture described by most of the other authors. All 3 patients did have some tendency toward an increase in the number of stools during the year preceding their visits to the clinic. It is our feeling that the absence of positive results of laboratory studies in these cases is referable to the fact that the disease of the patients was at the time we saw them in a relatively early stage.

Pathogenesis. Although the gross and microscopic pathological observations have been adequately described and although the essential finding is that of intracellular and extracellular fat associated with the features of a chronic inflammatory reaction the nature of the lipoid and the manner in which it arrives in the interstitial tissues of the involved organs are unknown. Several theories have been advanced to explain these features. Sailer and McGann said. The essence of the pathological process appears to be a local necrosis of the fat tissue with liberation of lipolytic ferments from the damaged cells. These authors however did not attempt to explain either how this necrosis is brought about or the nature of the ferments. Jarcho believed that dilatation of the lymphatics either obstructive or congenital is the essential characteristic. Hill agreed with this

is our impression that in all 3 cases the disease is in a relatively early stage it is hoped that further study of the patients concerned will throw some light on the true nature of the disease.

The surgical approach for the treatment of hiatal hernia. a) The abdominal wall is incised vertically. b) The abdominal wall is incised transversely. c) The abdominal wall is incised transversely with a horizontal extension. d) The abdominal wall is incised transversely with a central vertical extension. e) The abdominal wall is incised transversely with a central vertical extension and a small incision on the right. f) The abdominal wall is incised transversely with a central vertical extension and a small incision on the right. g) The abdominal wall is incised transversely with a central vertical extension and a small incision on the right.

geal wall at this point of pressure. The cricoid cartilage does not rest against the same vertebra or vertebral joint in all individuals. Its position depends on the stature of the person and the length of neck. It may rest against the lower border of the fourth cervical vertebra, but usually rests about opposite the fifth joint although it may be lower. There is some reason to believe that in individuals with more than average anterior curvature of the cervical spine, the cricoid cartilage rests more firmly against the spine.

Further reasons are that the upper portion of the posterior surface of the cricoid cartilage does not rest against the spine as does the lower portion, and it is here that herniation occurs. Just below the lower border of the cricoid cartilage the transverse fibers of the constrictor pass beneath the cartilage creating a shelf like fold. Chevalier Jackson has designated this portion of the muscle described as a pinchcock muscle, which closes the opening of the esophagus except during swallowing and regurgitation and believes that the muscle does not always co-ordinate its functions with the fibers of the inferior constrictors which are above the transverse fibers and have the general description of an inverted V.

Diverticula occur three times as frequently in men as in women. The male larynx is, on the average, one and one-half times the antero-posterior diameter of the female. Men are more muscular and the larynx is consequently held more firmly in contact with the spine. I recently saw a man who sustained a compression fracture of the fifth cervical vertebra with slight anterior displacement of the body of the vertebra, the pressure of which caused a bilateral recurrent nerve paralysis and within a few days necessitated a tracheotomy. I have seen decubitus ulcers develop in the esophagus or hypopharynx, on the posterior surface of the cricoid cartilage, from the pressure of a nasal feeding tube. In one instance, a bilateral cord paralysis resulted, in the other a unilateral paralysis. Other cases are reported resulting in mediastinitis. Surgical literature abounds with reports of such complications. The development of such ulcers serves to prove the firmness with which the cricoid cartilage is held in contact with the spine. I

do not know that it is a matter of importance as to whether or not one wishes to think of the constrictor mechanism at the junction of the pharynx and esophagus as comprising one or two muscles. It is mentioned only because the foregoing explanation of the etiology of the pharyngoesophageal diverticula seems more logical than that of a congenital hiatus in the mechanism. For proof of the firmness with which the larynx is held against the spine, simply grasp your own larynx between your thumb and index finger. It is easily displaced laterally. Now try to press it backward, and you will see that it is held firmly against the spine.

While making fluoroscopic examinations of patients with diverticula of the esophagus it was observed that the first swallow of barium mixture entered the diverticulum and only when it was filled did any pass into the esophagus, and that the fluid level at the opening of the sac approximated the width of the esophagus.

The spill-over of barium mixture from the opening in the sac, when observed under the fluoroscope, is an accurate measure of the width of the diverticulum opening. If an x ray photograph be made at the moment when the diverticulum is completely filled the fluid level will represent an accurate determination of the width of the opening. These observations caused me to alter my plan of dealing with the neck of the amputated diverticulum. In intestinal surgery sound principles dictate that the surgical closures of the bowel be done in a manner so as to create the least disturbance of the lumen of the bowel. The same principle applies to esophageal surgery.

Jackson and Jackson in the book entitled *Diseases of the Nose Throat and Ear* page 594, published in 1945 state "The esophagoscope will without difficulty enter the sac which is really the whole bottom of the pharynx, and will be arrested by the blind end of the pouch, the depth of which may be from 4 to 10 cm. The opening at the mouth of the sac, so dominates the hypopharynx that the passage of rigid instruments either for the purpose of examination or as part of operative technique, is a dangerous procedure except in the hands of those highly skilled in the use of

such instruments I have seen one patient who died as a result of mediastinal infection caused by perforation of the sac by passage of an esophagoscope through the pouch of the diverticulum. Some surgeons have recommended insertion of an illuminated instrument into the sac as a means of identification during its removal. Because of such accidents I would hesitate to employ that method.

In a majority of instances, diverticula are said to shift toward the left side of the midline of the neck. It is my opinion that this tendency is due to the fact that the distended sac bulges in the direction of least resistance which is to the left side. The left common carotid artery is farther removed from the trachea and esophagus than the right. The innominate artery and the left common carotid both arise from the arch of the aorta, on the left side of the midline. The innominate artery crosses in front of the trachea and divides into the right common carotid and subclavian. A line from the point of origin of this vessel to the foramen lacerum crosses the trachea and lies closer to its right border, than a similar line following the course of the left common carotid, which runs an almost perpendicular course from its point of origin to the corresponding foramen on the left side. The only diverticulum which I have encountered, causing a visible bulge, in the neck protruded to the right. For a right handed surgeon the regions and structures lying behind the larynx, pharynx and esophagus are easier to approach from the left side.

The preoperative preparation of the patient is important. Only liquid and soft foods should be given for at least 24 hours before operation. The evening before operation the patient should be instructed to lavage the sac on two or three occasions by swallowing water then lie down and empty the sac by strong swallowing efforts. One hour later 1 or 2 drams of a 10 to 20 per cent solution of tincture of metaphen, or tincture of merthiolate is administered with instructions to swallow it with one effort and to refrain from any effort to empty the sac. This is done for the purpose of reducing the bacterial content of the sac. How effective this is I do not know. In any event it does no harm. In our experience no infections or fistulas have occurred following

the one stage operation. A high percentage of the wounds following the two stage operation have had some degree of infection. This is believed to be due to the presence of gauze packing placed in the wound and left in place for a period of a week or more.

TECHNIQUES

Either local or general anesthesia may be used in the operation. My preference is sodium pentothal. The combination of nitrous oxide and ether is also satisfactory. Inflammable gases are undesirable because the cautery or coagulation current is a valuable agent in sealing the severed end of the sac. Local block anesthesia is satisfactory. It has one advantage in that the conscious patient's co-operation can be secured during the exposure of the neck of the sac, and determination of where the neck of the sac begins and the wall of the esophagus ends, is more easily made. The act of swallowing helps in determining the junction point. A suction device should be present for the purpose of removing from the pharynx, any contents of the sac which may be extruded into the pharynx, during manipulation of the sac.

As a rule the left side is the location of choice for making the incision. However, if by fluoroscopy or other examination the sac seems to lie more to the right, a right side incision becomes the location of choice. An incision 2 1/2 to 3 inches long, is made just anterior to the border of the sternomastoid muscle. Some surgeons prefer a transverse incision which results in a better scar. The incision extends through the skin platysma muscle, and deep cervical fascia. The omohyoid muscle is ligated, divided and separated from the sternothyroid muscle. The muscle is retracted outward the exposed outer border of the thyroid gland is retracted forward. The middle thyroid vein and inferior thyroid artery are ligated and divided if in the way. I have not always found this necessary. The carotid sheath is separated from the esophagus by passing the finger upward and downward along the space between it and the common carotid artery. The dissection should be carried high enough to expose the lateral border of the larynx and those fibers of the

inferior constrictor which surround the hypopharynx. This exposes the lateral borders of the esophagus and sac, except in cases of small diverticula. In the event the sac is not readily identified the loose space behind the esophagus and larynx should be opened or separated and the finger passed upward until the lower border of the cricoid cartilage is felt. The neck of the sac will always be found in the region of this constant point of identification.

A diverticulum begins as a small budlike bulge in the posterior wall of the hypopharynx or the upper margin of the esophagus. As it enlarges, the fibers of the inferior constrictor become further separated by the enlarging neck of the sac. Some of the thinned fibers fan out over the neck on its upper and lateral surfaces. A very sharp angle is created on the lower or undersurface of the neck of the sac where it leaves the esophagus. At this point some of the transverse fibers become rolled into a sort of bundle or cord over which the neck of the sac is suspended. This bundle of fibers should be divided and laterally separated and later may be used to cover the line of sutures closing the amputated neck of the sac. They should not be left to create another shelf like fold in the posterior wall of the esophagus. All other muscle fibers should be removed from the neck of the sac so as to provide a good view of its entire circumference.

It is important to determine carefully where the neck of the sac begins and the wall of the hypopharynx or esophagus ends. Caution should be exercised in removing muscle fibers from the neck of the sac, as it is quite thin and easily perforated. When the junction point has been determined it will be observed that the neck of the sac is practically the same size width or diameter as the esophagus.

The method of closing the neck of the sac is of greatest importance. If as has been recommended by some surgeons a transfixion and ligation suture be used, then practically one half the circumference of the esophagus may have been destroyed and an immediate narrowing or partial stricture created. If the transfixion and ligation suture is too far removed from the esophageal wall, a dimple will result, which is an invitation for recurrence of the diverticulum.

During the last 3 years I have devised and used a method of removing the sac and closing its neck that has proved entirely satisfactory. This procedure is based on sound anatomic and surgical principles a description follows.

In the resting state the opening of the sac is not a small round hole in the posterior wall of the esophagus but an elliptical slit occupying the entire diameter of the esophagus (see Fig 1 d). When the neck of the sac has been entirely freed and traction has been made upon its fundus the elliptical opening becomes rounded because of traction. The fundus is then grasped with an ordinary pair of triangular bladed forceps the sac is freed and the surrounding muscle fibers divided as previously described. It should be remembered that at the point of junction the esophagus and diverticulum make up a double barrelled tubular arrangement comprising two flattened tubes each about 1 inch in diameter one of which is immediately in front of the other. When the sac is freed and traction is put upon it instead of the barrels occupying a parallel position the sac then occupies a right angle position. A narrow bladed forceps of the Rankin or similar type is placed across the neck of the sac at the point of junction. This forceps does not interfere with or include any of the circumferential wall of the esophagus, and no narrowing or stricture is produced. It leaves the diameter and circumference undisturbed. A second forceps is placed parallel to the first and the neck of the sac is amputated between the two. The cut edge of the sac is sealed by electrocoagulation and painted with tincture of metaphen. A No. 00 chromic cat gut suture on an atraumatic needle is passed through both walls of the remaining amputated stump immediately behind, and next to the lock of the forceps. It is tied and continued for a couple of loose turns. This forceps is then removed. The suture is tightened and continued as a running suture (Fig 1 g) where it is again tied at the other side of the amputated neck of the sac. The suture should not be pulled taut enough to cause puckering of the closure. A second row of a similar running stitch is then placed infolding the first (Fig 1 h). A few interrupted sutures, picking up the divided muscle fibers may be used to

further reinforce the closure this, however, is not important. A little confusion may be encountered in placing the forcep at a right angle across the neck of the sac. This results because the upper end of the esophagus and the hypopharynx are anchored respectively to the posterior surface of the cricoid cartilage and the lateral borders of the thyroid cartilage. The esophagus therefore, cannot be rotated as a flattened tube when tension is made on the sac. One must make allowance for the altered relationship of the sac and the esophagus at this stage of the operation. It may be found convenient to place the forceps somewhat diagonally upward and downward, across the neck of the sac.

At this time a small feeding tube may be introduced through one nostril, and guided down the esophagus. We have not regularly used a feeding tube and are not convinced that it is necessary or even desirable. When used, 4 days has been the maximum time it has been left in place. When the closure is complete the wound is lavaged and a few sulfathiazole crystals are dusted (not dumped) into the wound. Penicillin may be substituted. A small Penrose drain is inserted and left in place for 48 hours. The omohyoid muscle is sutured and the wound is closed with interrupted catgut and skin clips.

Nothing by mouth is given for 2 days. If a feeding tube is used, liquids are administered through it for 3 or 4 days. If not used intravenous fluids are given for 48 hours. Fluids by mouth are begun in 48 hours.

During the last 3 years this operative procedure has been employed on 11 patients with

no infections, no fistulas or other complication. Postoperative dilations have not been necessary. The patients were hospitalized for 3½ to 7 days.

Prior to that time when the two stage operation was employed three fistulas and a high percentage of infected wounds resulted. One death occurred several years ago in a very much emaciated arteriosclerotic woman aged 75 years the result of a coronary occlusion 24 hours after the first stage of an uncomplicated operation. This cannot be attributed to the two stage method.

In my experience, the removal of pharyngo-esophageal diverticula has not been a difficult operation except in the case of one small diverticulum which when empty was so contracted that it lay immediately behind the larynx and was difficult to find. I suggest that if one has difficulty in locating the sac, the space behind the upper end of the esophagus be opened. This is easily done because of the loose connective tissue occupying that region. Then pass the finger upward behind the esophagus and larynx until the lower border of the cricoid cartilage is felt. The neck of the sac will always be found in the immediate vicinity of the lower border of the cricoid cartilage. In large diverticula, the sac is usually easily identified and the above procedure will be unnecessary.

If one is familiar with the anatomy of this region and understands the mechanics of the pharynx and esophagus and the development of an esophageal diverticulum, there should be no difficulty in effecting a cure by a one stage operation.

TUMORS OF THE GASTROINTESTINAL TRACT

A Survey of 813 in Persons of Military Age during World War II

J. C. EHRLICH Major M.C., A.U.S. and O. B. HUNTER Jr Major M.C., A.U.S.,
Washington, District of Columbia

THE gastrointestinal tract proved to be a favorable site for the development of tumors in persons of the Army age group. As a result, specimens from the digestive tract made up one of the largest sections of the entire collection for the period of World War II at the Army Institute of Pathology. It seemed appropriate, therefore, to make a thorough survey of these tumors emphasizing their relative frequency, anatomic distribution, histologic characteristics, and pertinent clinical features. By this study many well known facts have been given emphasis and a number of little known facts have been brought to light and to some extent clarified.

Eight hundred and thirteen tumors of the gastrointestinal tract arising in Army personnel between the ages of 18 and 38 were examined at the Institute between December 7, 1941 and August 15, 1945. Anatomically the lesions were situated between the pharyngo-esophageal junction and the anus, those arising in the buccal cavity and pharynx form the basis of a separate report. Almost all of these tumors constituted a primary, new disease in a previously healthy individual; a few were discovered at autopsy in patients dying from other causes. The diagnoses under which the specimens were classified can be accepted with a considerable degree of finality in view of the fact that most of the lesions were not of controversial character.

MATERIAL

The statistical studies incorporated herein are based entirely on the records at the Army Institute of Pathology. No attempt was made to conduct an independent analysis of the gross anatomic material or the histologic sections. In the vast majority of cases a reasonable unanimity of opinion was reached by the

From The Army Institute of Pathology, Washington, D. C.

pathologists who reviewed the material. In some instances unresolved differences of opinion were evident in the records and in such cases it was necessary for the authors to decide in the light of available information in which category to place the lesion for statistical purposes.

The 813 lesions selected for analysis occurred almost entirely in enlisted or officer personnel of the Army of the United States. Occasional specimens were obtained from prisoners of war and internees of relocation centers. Seven hundred and forty nine were found in white, 58 in negro and 6 in mongolian patients. This distribution is consistent with the ratio in overall Army population. Forty two of the patients were women.

The lesions were classified from a cytogenic standpoint and the results are summarized in Table I. A few specimens not strictly regarded as neoplasms were included for their general clinical and morphologic interest. In Table V all the varieties of tumor found in the gastrointestinal tract are listed according to their anatomic location.

CARCINOMA

There were 441 carcinomas in the group; they are subdivided by location in the gastrointestinal tract and by age of the patient in Table II and the percentage of fatality is listed. It is evident in this table that approximately half of the cancers of the large intestine occurred in the rectum (171/169). Carcinomas of the large intestine (including rectum) made up 77 per cent of the malignant epithelial tumors.

There were 26 cancers in the 18 to 30 year age group, 198 in the 31 to 35 year group and 217 in the 36 to 38 year group. In Chart 1 the same figures are expressed per 100,000 mean strength of the Army from December 7, 1941 to August 15, 1945. According to these

SURGERY GYNECOLOGY AND OBSTETRICS

est recorded was 2 weeks and the longest 26 months.

The location of the primary tumors is summarized in Chart 2. A comparison with published statistics shows a rough similarity in distribution.

In 45 cases the histologic variety was specified the findings are presented in Table III.

A review of the clinical data incorporated in the records brought out no unusual details. Positive roentgenologic interpretations were made in 31 cases. 5 of the tumors perforated spontaneously. ascites was recorded in 31.

Small intestine. There were 9 cases in which the diagnosis was primary carcinoma of the small intestine. 8 of them were adenocarcinoma and 1 was a mucous cell carcinoma. Two arose in the duodenum, 4 in the jejunum, and 3 in the ileum. There were 7 white males, 1 white female and 1 mongolian male in the group. Four of these patients are known to have died. the duration from onset of symptoms to death being 2, 5, 6 and 13 months. In one of these cases the diagnosis was confirmed on the basis of malignant cells in the sediment from ascitic fluid.

TABLE III.—HISTOLOGIC TYPES OF GASTRIC CARCINOMAS

Adenomatous	39	Colloid.
Scirrhus	3	Polypoid
Medullary	3	Anaplastic
Ulcer		

Appendix. Seven carcinomas of the appendix were reviewed. 1 from a patient under 21, 1 from patients in the third decade and 3 in the fourth. Two of these patients died the known duration of the disease being 5 and 13 months. The clinical diagnosis of acute appendicitis was made in almost every case and the true nature of the disease discovered only at operation or post mortem. Histologically, 5 were mucinous in 1 of the latter pseudomyxomatous peritoneal implants were encountered.

Large intestine. From the large intestine (not including the rectum and rectosigmoid) 171 carcinomas were removed. Ten of these occurred in patients under 21, 72 in patients in the third decade, and 89 in patients between 31 and 38. The total of 171 cases constitutes almost 40 per cent of all tumors of the gastrointestinal tract. The general distribution of these tumors is shown in Chart 3 and the relative percentage in each anatomic location follows rather closely those in published surveys (e.g. Oberndorfer etc.) The histologic types encountered are indicated in Table IV.

TABLE IV.—HISTOLOGIC TYPES OF CARCINOMA OF THE LARGE INTESTINE

3	Adenomatous	99	Papillary adenomatous	5

			Undifferentiated	

Chart 3. Carcinomas of the large intestine in Army Institute of Pathology series, at left compared with Oberndorfer's figures, at right.

There were 12 females in this series all other patients were white males except 17 negro males and 2 mongolians. These figures are approximately the racial ratio in the population

At the time figures were compiled for the survey there were 67 known fatalities. Death had occurred at an average interval of 8 months from the onset of the disease the longest duration recorded was 48 months

*Multiple sites in G-I tract.

pochochondrial distress. Magnesium sulfate in the duodenum relieved the distress and produced a copious bile flow.

Only manometric studies can make a diagnosis of motor dysfunction of the sphincter of Oddi at present. In the presence of a gall bladder delayed evacuation during a cholecystogram has been considered of diagnostic aid but evidence is contradictory and meager. The stimulus of a fatty meal is too variable for standardization of the procedure. Visualization of the hepatic ducts with a normal gall bladder *in situ* may occur with or without pain, generally the latter and is, therefore, neither helpful nor easy to explain.

The author suggests studying such patients with secretin-cholecystokinin as outlined in conjunction with cholecystography and attempts to visualize the hepatic ducts during cholecystography by feeding three egg yolks in milk. The latter could also be introduced into the duodenum directly and the patient given morphine hypodermically to contract the sphincter of Oddi in order to observe whether pain occurs during gall bladder contraction.

Postcholecystectomy colic in the absence of organic causes, or gross liver or bile duct disease must be considered as being due to sphincter spasm. In some cases if the colic is induced by 1/4 gr. of morphine the diagnosis may be strongly suspected. A more radioactive dye than now exists and which would be excreted by the liver in sufficient quantities to visualize the ducts without concentration should help in the diagnosis.

FREDERICK C. HORTON, M.D.

Varco, R. L.: Intermittent External Biliary Drainage for Relief of Pruritus in Certain Chronic Disorders of the Liver. *Surgery* 1947 2: 143.

Pruritus caused by certain chronic disorders of either the hepatic parenchyma or the intrahepatic biliary system (chronic hepatitis or cirrhosis) causes unremitting annoyance and is intractable to the therapy now customarily employed (dihydroergotamine (intramuscular), procaine hydrochloride (intravenous), sedatives, hypnotics and analgesics).

Varco reasoned that if it is true that the intractable pruritus is caused by the abnormal retention of bile salts then the development of a method for the reduction of the serum bile salt should constitute a rational therapeutic approach to this problem. As a result of the previous studies by Whipple and his collaborators, it was believed that because 90 per cent of the total quantity of bile salts secreted each 24 hours is resorbed from the intestinal tract, recirculated through the liver and then re-eliminated in the bile, only pre-enteric deviation of the bile would reduce the serum bile salt level.

Upon translating these conjectures into surgical procedures it was determined that intermittent external biliary drainage suffices to attain and maintain prompt and virtually complete relief from the pruritus of pruritus under consideration. The most active operative procedure for this purpose is cystostomy and drainage of the common bile duct with a T-tube size 1 to 2 French.

Small quantities of bile salts were given orally upon 3 occasions to patients who had an external biliary fistula. Pruritus promptly returned and then disappeared with the maintenance of intermittent external biliary drainage. ROBERT TURNER, M.D.

Mallet-Guy P., and Jeanjean R.: Surgical Eventualities in So-Called "Medical" Jaundice (Eventualités chirurgicales dans les ictères dit médicaux). *Lyon chir.*, 1946, 41: 189.

The author discusses the possible surgical complications of infectious jaundice, particularly dyspeptic disturbances persisting after subsidence of infectious jaundice, relapsing episodes of jaundice, and abnormal prolongation of jaundice.

If surgical exploration for one of these conditions fails to reveal a lesion in the biliary tract or the head of the pancreas, the symptoms are probably due to (1) hypertony of the sphincter of Oddi, (2) hypotony of the sphincter of Oddi, or (3) a variable degree of compression of the common bile duct usually associated with a chronic pancreatitis.

These may be differentiated from one another by manometric and roentgenographic studies of the biliary duct system made by cannulating the biliary tree at the time of operation. Usually the surgeon will find a precise disturbance of biliary function, either a relative degree of obstruction due to pancreatitis or a hypertonic or hypotonic sphincter of Oddi.

For obstruction due to pancreatitis, cholecystectomy is indicated. Biliary anastomosis is not indicated unless the obstruction is great enough to indicate some other condition than infectious jaundice. Similarly for cases of hypertonicity of the sphincter cholecystectomy appears to interrupt the evolution of sphincter spasm. However when the hypertonicity is too severe to be relieved by simple drainage transduodenal sphincterotomy is preferable and restores a more normal tonicity of the sphincter. If, on the other hand a state of atony of the biliary tract and sphincter exists, simple drainage of the gall bladder is the preferred treatment. In some of these cases splanchicectomy also is of value.

EDWARD W. GIBBS, M.D.

Clavel, G., and Dumas, J.: Acute Calculous Cholecystitis in Children (La cholecystite calculuse aiguë chez l'enfant). *Lyon chir.* 1946, 41: 412.

Acute calculous cholecystitis is rare in infants and children. The authors collected 103 cases and found that the greatest incidence of lithiasis in children occurred prior to the age of 1 year and just before the age of 15 years. Calculous cholecystitis is rare before the fifth year of age. Before the age of 10 acute cholecystitis occurs more frequently in males, but after the age of 10 the incidence is greatest in females.

The classical list of predisposing causes of calculous cholecystitis in children includes typhoid fever, scarletina, grippé, pneumonia, upper respiratory infections, gastrointestinal illness, intestinal parasites, appendicitis, and heredity. However in many cases

neither the antecedent history nor the operative findings suggested any definite predisposing cause.

There is nothing characteristic about the pathological findings in infants. Calculi of varying size number, and chemical composition are described. Examination of the gall bladder wall and lumen discloses the characteristic findings of acute cholecystitis, of catarrhal, suppurative or gangrenous type.

There is no doubt of the congenital origin of calculi for they have been described in the newborn and even in the fetus. In infants and children the pathogenesis appears to be the same as in adults except for the sudden increase in frequency of the disease in girls just before puberty which suggests an endocrine or vagosympathetic disturbance.

In a clinical study of 22 cases the authors found 8 cases of suppurative cholecystitis, 1 case of gangrenous cholecystitis, 10 cases of catarrhal cholecystitis, and 3 cases of cholecystitis with the complication of perforation or fistula formation.

Appendicitis is the most common diagnostic error. However in infants there are a certain number of gall bladder syndromes without lithiasis namely typhoid cholecystitis, scarlatina cholecystitis, external compression of the biliary tract by adenopathy, intestinal worms and acute noncalculous cholecystitis. Also, lithiasis is seen without cholecystitis and in some cases of hemolytic icterus.

The diagnosis is based on symptoms of pain, constipation, high fever and leucocytosis with a predominance of polymorphonuclear cells added to the picture of noncomplicated lithiasis producing painful crises and hepatic colic. If this picture can be distinguished from other acute peritoneal syndromes by its localization and clinical history an accurate diagnosis can be made.

Congenital lithiasis often associated with malformations of the biliary passages, is frequently fatal. Acquired cholelithiasis, if recognized and treated surgically bears a good prognosis.

The authors recommend early operation. Although cholecystostomy might at first seem to be particularly indicated in infants and children the frequently encountered advanced changes in the gall bladder wall will often necessitate removal of the gall bladder.

EDWARD W. GRANT, M.D.

Muir J. B. G.: Surgical Hazards in the Treatment of Cholecystitis and Cholelithiasis. *Austral N Zealand J Surg.*, 1946, 16, 14.

The author reviews the surgical hazards and results of 421 operations on the biliary tract. The pathological condition, the type of operation performed, and the causes of death in each group are discussed.

Two hundred and seventy five cholecystectomies were performed for chronic cholecystitis and cholelithiasis, with 6 deaths—one due to pulmonary embolism, 3 to hepatorenal syndromes, and 2 to internal hemorrhage. Cholecystostomies were done in 3 cases, with no deaths.

When surgical treatment was carried out in the presence of acute inflammatory changes in the gall

bladder the mortality rose from 2.18 per cent to 18.4 per cent. In all, 103 cases were recorded in this group and the pathological findings at operation included acute cholecystitis with commencing gangrene, perforation and peritonitis, cholecystoduodenal fistula, pancreatitis communicating with liver hydatid and empyema of the gall bladder.

Cholecystectomy performed in patients with acute cholecystitis carried with it a mortality of 20.6 per cent whereas the mortality following cholecystostomy was 15 per cent, despite the fact that it was selected for the poor risk cases.

The question whether cholecystitis in the acute stage should be treated conservatively or with immediate operation is discussed at length. Muir believes that generalization is impossible and that each case of acute cholecystitis should be treated on its merits, the patient being under observation in the hospital. Consideration of the local pathological process should always be borne in mind. Apart from a small proportion of welchii infections the organisms causing cholecystitis are usually *Bacillus coli* and streptococci of low virulence. In the early stages the inflammatory process is catarrhal in type and limited to the mucous membrane and submucous tissue. Provided there is no obstruction the tendency in first attacks is to subside, leaving local adhesions on the peritoneal surface of the organ and a thicker gall bladder wall.

The theory is advanced that in a number of cases of acute cholecystitis, mechanical and circulatory effects rather than bacterial infection are responsible for the principal pathological changes. The veins draining the gall bladder are much more closely incorporated with the cystic duct than is the cystic artery and so lead to edema, congestion, and infarction.

The necessity for immediate operation on the tender palpable gall bladder it is argued, is based on the fact that the tension in the gall bladder may become so great that the blood supply is compressed resulting in gangrene, that there is seldom any clinical indication during an attack of acute cholecystitis that pus is present, and that perforation in a "watched" case is frequently the first indication that the attack is not subsiding.

These complications of nonresolving acute cholecystitis are arguments in favor of early surgical intervention. There is little doubt that in a younger type of patient, whose liver function has not been impaired by numerous attacks of cholangitis, cholecystectomy performed in the early catarrhal stage, when the normal surgical anatomy is not badly obscured by inflammatory exudate—that is, during the first forty-eight hours—is not a very formidable technical undertaking and the risk is not great. It must be remembered, however, that these patients are not always seen at that stage and have usually been sick at home for several days before admission to the hospital, so that the day of admission is by no means the first day of the attack. A careful history and assessment of the local pathological process as a

guide to the time of operation are therefore most necessary. If the patient is not seen until the fifth or sixth day the gall bladder will be surrounded by adhesions and considerable local serofibrinous exudate will be present. There will be difficulty in securing the proper plane of separation of the gall bladder from the liver and, also, owing to troublesome oozing and friability of tissue in subsequently peritonizing the gall-bladder fossa when the organ has been removed. In such cases the hepatoduodenal ligament is always swollen and edematous, and the veins between its folds are engorged and bleed readily quite unlike minor vessels encountered there in cases of chronic cholecystitis. The cystic lymph glands will also be enlarged and inflamed.

These facts will make the clear dissection of the cystic duct a difficult matter and failure to secure the cystic artery and the perpetual bugbear of damage to the common bile duct become real dangers. In such cases these dangers can be avoided by performing a cholecystostomy (if necessary under local anesthesia) should immediate surgery be warranted by the progress of the condition.

Careful analysis of the records of acute cases in the series showed that one-half of the operations were carried out within 48 hours of admission of the patient to the hospital, and in about 50 per cent of the acute cases in which operation was performed actual empyema of the gall bladder existed. Because of this, it is believed that had cholecystostomy been performed only as a temporary life-saving measure, instead of cholecystectomy, 5 deaths from reactionary hemorrhage and 3 from biliary peritonitis would presumably not have occurred and the mortality figure would have been reduced to 11.6 per cent.

Conversely, it is argued that of 243 admissions on the medical side of the hospital for cholecystitis, and investigated for suspected cholelithiasis during this same period, the condition in 54 patients was diagnosed as acute cholecystitis, and all except 3 recovered satisfactorily which confirms the estimate that only from 5 to 7 per cent of acute cases progress to a stage requiring urgent operation.

In the series, exploration of the common bile duct for the removal of stones was combined with cholecystectomy and cholecystostomy in 34 cases with 7 deaths—a mortality rate of 21 per cent—which is a very serious rise compared with 2.15 per cent in uncomplicated cholecystectomy.

Three patients were operated upon for stones over looked in the common bile duct at a previous cholecystectomy. In each case the second operation was performed within 2 years of the previous operation. In 1 case the stone was impacted in the sphincter of Oddi, and was removed by a transduodenal approach. In the 2 other cases it was removed through the supra-duodenal portion of the duct. All 3 patients had suffered from repeated attacks of intermittent jaundice and pain, with occasional attacks of fever since cholecystectomy and all made a good recovery.

Two patients with common duct stricture were listed for treatment following cholecystectomy

performed for acute cholecystitis, 9 months and 1 year previously. One patient had submitted to 2 operations to relieve the stricture. Temporary success for 6 months was obtained but the old symptoms returned and death from liver failure took place 1 year later. The second patient is well 2 years after operation, but from time to time suffers from attacks resembling mild biliary colic.

The causes of death in order of frequency were pulmonary complications such as embolus and pneumonia, internal hemorrhage (secondary and reactionary) liver failure, hepatorenal syndrome, uremia, biliary peritonitis congestive heart failure hematemesis, and hyperpyrexia.

STEPHEN A. ZIEGLER, M.D.

Tanna, I. T.: Splenectomy: An Analysis of 38 Cases. *Surgery* 1947 1: 46.

The author analyzed the results of 38 splenectomies performed at the Charity Hospital New Orleans during the period from January 1, 1939 through 1945 exclusive of those done for trauma or those done during the course of esophagectomy or total gastrectomy.

Eleven splenectomies were done for congenital hemolytic anemia. The follow-up studies, ranging from 3 months to 3 years, showed excellent results in 8 of the 11 patients. There was slight improvement in 1 patient in whom it was believed that accessory spleens had not been removed and 2 patients died. One patient died immediately after operation from peritonitis and pericarditis, and the other died 9 years later.

One splenectomy was performed for acquired hemolytic anemia. This patient died on the first post operative day from hemorrhage caused by a slipped ligature upon the splenic pedicle.

Four splenectomies were performed for idiopathic thrombocytopenic purpura. These were done under general anesthesia. All of the patients had received blood transfusions before, during, and after the operation. The results were excellent in 3 patients the fourth one died as a result of continuous oozing from the splenic bed.

Ten splenectomies were performed for Banti's disease. Only 4 patients obtained fairly good results from this procedure. 4 patients showed no improvement in their condition, and 2 died.

In these cases it is necessary to determine the site of portal obstruction before rational therapy can be instituted. One can predict, on the basis of liver function chemistry whether the portal hypertension is due to intrahepatic (portal cirrhosis) or extra-hepatic portal bed block. If the liver is the site of the portal block i.e. portal cirrhosis is manifested by deficient liver function, splenectomy alone will not effect a cure. In this type of case it is necessary to perform a portocaval shunt in addition to the splenectomy. The nonstature method of anastomosis between the portal and caval systems can be effected by the use of vitallium tubes. Even when the block is extrahepatic but proximal to the entrance of the

coronary vein into the portal system, splenectomy alone will not effect a cure. It is only in the case in which the obstruction is distal to the entrance of the coronary vein into the splenic vein that splenectomy alone will give a satisfactory result with relief of hematemesis, anemia, leucopenia, and thrombocytopenia.

One splenectomy was done for splenic neutropenia which resulted in marked improvement of the general condition of the patient.

Six splenectomies were performed for sickle-cell anemia, with poor results. The value of splenectomy in this condition is doubted by most authorities, because lymph nodes and other reticuloendothelial tissue may carry on the phagocytic function of the spleen even if it is conceded that the spleen is responsible for deterioration of the red blood cells.

One splenectomy was performed for torsion of the spleen. At operation the spleen was enlarged and twisted 3 times upon itself. Pathologically the spleen showed thrombosis of the hilar vessels and massive splenic infarction. The patient made a remarkable recovery.

One splenectomy for aleucemic leucemia and 3 splenectomies for splenomegaly of undetermined etiology gave poor results.

On the basis of his study Tanna concluded that splenectomy is definitely indicated for congenital

hemolytic anemia, idiopathic thrombocytopenic purpura, splenic neutropenia, and splenic torsion. Careful evaluation is in order before splenectomy is performed for Banti's disease. Splenectomy is of little or no value in patients with sickle cell anemia, aleucemic leucemia, and those with splenomegaly of unknown origin.

MISCELLANEOUS

Sperling L. Basher L. H. and Zimmerman H.: *Surgery of War Wounds of the Abdomen. Surg. 1947 21: 258.*

In 100 consecutive cases of abdominal injury 14 deaths occurred. Eleven deaths occurred among 74 cases of injury to multiple hollow viscera. This mortality rate is much lower than that of the first World War and compares favorably with recent publications from World War II.

It is difficult to ascribe the lowering of the mortality rate to any one specific factor. penicillin, sulfadiazine, blood plasma and watchful postoperative treatment were all important factors. However the proper treatment of shock was probably the most important single factor. Adequate decompression of the bowel by gastric suction siphonage before, during and after surgery surely played an important role.

SAMUEL KAHN, M.D.

GYNECOLOGY

UTERUS

Mazzullo, B.: Cancer of the Uterus at a Youthful Age. A Gynecostatistical Contribution (Il cancro dell'utero in età giovanile. Contributo ginecostatistico). *Gli ologia, Tor* 1946 13 33

A clinical report of 4 cases of carcinoma of the uterus occurring in young women of less than 30 years of age is given. These cases were among a series of 109 cases of carcinoma of the uterus treated in the Obstetrical and Gynecological Clinic of the Maternity Hospital of Torino during the 10 year period between 1933 and 1942 and made up 3.6 per cent of the total number of cases of uterine cancer.

In a preface before presenting the individual cases, the author discusses carcinoma of the uterus in general and stresses the fact that this disease is not a postmenopausal disease, but one that occurs most frequently in women from 30 to 35 years of age, during the period of greatest sexual activity.

Case 1 was that of a housewife of 29 years with negative family and past histories, who had borne 3 normal children. Three months prior to entry into the hospital, the patient developed a fetid leucorrhoea streaked with blood which increased in amount and was finally succeeded by severe vaginal hemorrhages. She had begun to experience low back pain. Physical examination revealed the presence of enlarged inguinal lymph glands. Vaginal examination revealed a bloody vaginal discharge, a large indurated ulceration of the whole anterior lip and one-third of the posterior lip of the cervix; the uterus was not enlarged but there was dense parametrial infiltration. Biopsy revealed a spinocellular type of carcinoma of the cervix. A diagnosis of inoperable cancer of the cervix was made. The patient was treated with radium and x rays. She recovered satisfactorily and was discharged apparently free from her symptoms.

Case 2 was that of a housewife of 27 years with negative family and past histories who had borne 2 children. During the second pregnancy a carcinoma of the cervix was found which had been causing symptoms for about a year. The patient was given radium therapy, the pregnancy proceeded to term, and a normal child was delivered. Soon after delivery a blood streaked leucorrhoea developed and on vaginal examination an extensive ulceration of the whole anterior lip of the cervix was discovered; the uterus was not enlarged and it was mobile in all directions. There was no apparent parametrial infiltration. Biopsy revealed a spinocellular carcinoma of the cervix. A vaginal hysterectomy was done, and 35 days later the patient was discharged from the hospital. For three years follow-up examinations revealed no sign of return of the disease.

Case 3 was that of a 28 year old housewife with negative family and past histories, who had borne a normal child. A second pregnancy was interrupted

spontaneously and a curettage was performed. Two months later the patient developed an abundant blood streaked leucorrhoea, especially abundant after sexual intercourse. Vaginal examination revealed a fetid serousanguinous cervical discharge; the cervix presented a characteristic irregular ulceration of the posterior lip of the cervix, of hard consistency and friable. The body of the uterus was not enlarged, but it was mobile in all directions. The parametrium was free. Biopsy revealed a spinocellular carcinoma of the cervix. A vaginal hysterectomy was performed and 20 days later the patient was discharged from the hospital. Nothing further was seen of the patient as she failed to report for postoperative follow-up.

Case 4 was that of a 29 year old housewife with negative family and past histories she had borne 3 normal children. Two months before entry into the hospital, she developed a leucorrhoea and had subsequently suffered vaginal hemorrhages, especially severe after sexual intercourse and douching. She had developed pain radiating from the pelvic region to the suprapubic, inguinal, and lumbosacral regions. Physical examination revealed a compensated mitral insufficiency. Vaginal examination revealed a cervix with extensive ulceration characteristic of neoplasm. The body of the uterus was fixed and the parametrium was infiltrated. Biopsy revealed a spinocellular carcinoma of the cervix. The patient was given radium and x ray treatment, but she died 3 months after entry into the hospital of cardiac collapse.

These cases demonstrate that carcinoma of the uterine cervix affects young women at the height of their sexual activity. A family history of neoplastic tendencies is lacking. The patients have borne normal children. The initial sign of the disease is the development of a fetid, blood streaked leucorrhoea (all 4 cases) which rapidly increases in severity and finally is replaced by vaginal hemorrhage. General trauma as from accidents and local trauma as from sexual intercourse and douching serves to increase the bloody discharge. Pain (cases 1 and 4) is a late sign and usually denotes extension of the disease to the uterine body, the parametrium, and to the regional and inguinal lymph nodes. Vaginal examination reveals the extensive ulceration of the cervix characteristic of neoplasm (all 4 cases). The uterus is mobile and not enlarged (cases 2 and 3) if there has been no extension of the disease into this organ and the parametrium. If such extension has taken place (cases 1 and 4) the uterus is fixed and the parametrium infiltrated. Biopsy reveals a carcinoma of the cervix of the spinocellular type (all 4 cases).

Treatment given by the author consists of vaginal hysterectomy (cases 2 and 3) if the examination shows no sign of extension of the disease from its original focus. The patient in case 3 in this series was well 3 years postoperatively. The patient in case 3 disappeared from the control of the author and

no postoperative report is available. In cases in which the disease has extended from its original focus (cases 1 and 4) as is shown by fixation of the uterus, parametrial infiltration and enlargement of local and regional lymph nodes, x ray and radium treatment is given. Case 1 of this series was treated apparently successfully with radium and x rays. The patient in case 4, also with extension of disease into the body of the uterus and parametrium, died early after treatment from cardiac complications due to a long standing mitral insufficiency. Case 2 in which the patient was found to have carcinoma of the cervix during pregnancy was treated with radium and a normal child was delivered at term. The treatment given did not eradicate the disease as the patient developed a fetid blood streaked vaginal discharge shortly after delivery. She was then subjected to a vaginal hysterectomy. This leads the author to treat doubtful cases by complete hysterectomy (vaginal or abdominal) first and if signs of extension are present or suspected he resorts to x ray and radium treatment.

Every young woman who develops a fetid blood streaked leucorrhea should be subjected to a careful and thorough physical examination the gynecologist being mindful that this sign is the most important initial symptom of cancer of the cervix.

BLACKWELL MARKHAM M D

Pollack, R. S., and Taylor, H. C., Jr.: *Carcinoma of the Cervix during the First Two Decades of Life.* *Am. J. Obst.* 1947 55 135

The apparent tendency of cancer to manifest itself during the earlier decades of life is a fact that bears emphasis. It should be evident that no age barrier exists excluding the development of adult lesions in young people.

The authors report the occurrence of cancer of the cervix in an 18 year old woman. The patient presented symptoms of vaginal bleeding at irregular intervals for a period of 5 years before being seen by the authors. During this time she had been seen by several physicians but had never had a pelvic examination. Various forms of codocine therapy had been given. A biopsy was finally made, which revealed an adenocarcinoma of the cervix. Clinical examination placed the lesion in group 3. In spite of adequate radiological treatment she ran a slowly progressive downhill course.

Thirty cases of carcinoma of the cervix in women 20 years of age and younger are reviewed from the literature. The authors point out the fact that the diagnosis is too often delayed in these cases because of the patient's age. In spite of treatment the course was usually progressively downhill, and of this group only 4 patients have survived 5 years.

JOHN R. WOLFF M D

Miller N F., and Henderson C. W.: *Corpus Carcinoma.* *Am. J. Obst.* 1946 52 894.

The authors present a review of 322 cases of corpus carcinoma which have come under their care

since 1931 all patients have been traced. The plan of treatment was based on the assumptions that elimination of the primary neoplasm could best be achieved through complete surgical extirpation of the entire uterus tubes and ovaries and that supplemental irradiation therapy should be most beneficial when given prior to operation thereby causing widespread damage to cancer cells, minimizing manipulative spread at operation and at least partially obliterating the lymphatics. In the planned treatment of choice the decision to use deep x ray therapy in preference to radium was based on its known effectiveness in neoplasia of the cervix, its helpfulness in prolonging the lives of some patients with ovarian carcinomas and its broader field of irradiation which might also damage neoplastic cell masses sometimes found in the tubes and ovaries of patients with carcinoma of the uterus (7 times in 96 patients operated upon).

In the authors experience preoperative x ray therapy proved to be a valuable adjunct to total hysterectomy and bilateral salpingo-oophorectomy. In the treatment of carcinoma of the uterus. Its use clears up uterine infection, reduces the size of the uterus and decreases pelvic hyperemia thereby facilitating operation. It has not in any discernible way interfered with wound healing. Because for most patients this is an outpatient procedure the 3 weeks required for its administration is not a serious drawback.

The results obtained with preoperative x ray treatment warrant its continued use at least until some other combination or new form of therapy has proved to be more satisfactory. The use of very high voltage x rays as a preoperative measure in carcinoma of the uterus appears promising and should be explored further. On the basis of available data, the relative merits of preoperative x ray versus radium could not be stated.

ADnexAL AND PERIUTERINE CONDITIONS

Smith F. G.: *The Pathology and Physiology of Struma Ovarii.* *Arch. Surg.* 1946 53 603

Thyroid tissue develops fairly frequently in ovarian dermoids although it is usually no more than a microscopic portion of the tumor. There is however a rare type of ovarian tumor known as struma ovarii in which thyroid tissue is a major constituent. Some of these ovarian goiters are obvious teratomas containing besides thyroid, such tissues as skin teeth, brain and intestinal epithelium. Others consist entirely of thyroid or of thyroid in association with a cystoma. Gottschalk in 1899 described an ovarian tumor composed entirely of thyroidlike tissue.

It is the purpose of this paper to describe the pathologic changes and functional activity of thyroid tissue in ovarian tumors. The study is based on the investigation of a case of struma ovarii and an analysis of 152 previously published reports of cases. Ovarian tumors containing thyroid tissue occur at all ages. Merittens reported the case of a 6 year old

girl, and Heinsen that of a woman of 74. Dermoids constitute the largest group of tumors which exhibit thyroid tissue. Seventy six of the tabulated cases fall in this group. In 47 cases a serous or pseudomucinous cyst has been described in combination with a solid tumor consisting of thyroid tissue without other recognizable teratomatous elements. Thyroid tumors occurring alone, without cystoma and without other teratomatous elements (but not excepting bone or cartilage) are listed 26 times in the series. These are the cases of so-called pure struma ovarii. The smallest tumor of this sort was a 6 mm. nodule of thyroid tissue found by Masson and Mueller at autopsy of a 38 year old woman who had died of thyrotoxicosis and hepatic atrophy. Tumors the size of a child's head have been reported.

A tumor of the opposite ovary has been reported in 81 cases of struma ovarii. Thyroid tissue was present bilaterally in 6 cases.

Ascitic fluid was found in 26 cases an incidence of 17 per cent.

Dissemination of these tumors has occurred in a few instances. Three distinct types of metastasis have been found: local implants on the peritoneum and omentum, regional spread with nodules in the liver and distant metastasis.

Cervical goiter has been recorded 25 times in the entire series of 253 cases, an incidence of 10.3 per cent.

The tissue is identical with the structure of the thyroid gland. The colloid is homogeneous tends to retract from the epithelium, and is frequently vacuolated. The staining qualities are those of colloid, not mucin or pseudomucin. The struma is delicate, and interfollicular cells are numerous. There is evidence of various levels of physiologic activity. A histologic appearance of malignant growth has been described repeatedly. The borderline between physiologic and neoplastic processes is still vague. Graham considered invasion of the blood vessels the only reliable distinction between benign and malignant adenomas. Adenomatous proliferation with struma ovarii has been described.

Some of the otherwise pure thyroid, or cystoma with thyroid, tumors contained foci of calcification, or the formation of bone or cartilage. Since bone and cartilage may develop widely in the body the authors exclude this as a special quality of teratomas.

Investigation of the iodine content of the thyroid tissue has been undertaken in 32 cases. In 15 cases the results were negative qualitative tests were reported as giving positive results in 5 cases. 15 quantitative determinations have demonstrated iodine in varying amounts. The maximum values recorded are those of Emge (5.018 mgm. of iodine per gram of wet tissue) and of Masson and Mueller's first case (1.05 mgm. of iodine per gram of dry weight). These concentrations correspond to the iodine content of the normal adult thyroid gland.

Plaut's results indicate that in struma ovarii, as in the thyroid gland the biologic activity parallels the iodine content.

Symptoms of thyrotoxicosis have been frequently cited as evidence of the physiologic activity of struma ovarii. Seven patients seem to have shown significant alleviation of symptoms following operation.

The origin of thyroid tissue in ovarian tumors has been explained in various ways. It has been denied that the tissue is true thyroid. Gottschalk considered the tumor a follicularoma. In approximately half of the cases of struma ovarii the tumors exhibit other tissues obvious to foreign to the ovary. These tumors belong to the general class of teratomas. The ovarian tumors which contain only thyroid or thyroid with a cystoma are generally considered to be teratomas in which all other tissues have undergone regression.

A case is reported in detail and the literature is reviewed. There is a complete bibliography.

D. VINCE MORROW, M.D.

LINARD, R.: V. Metastatic Bilateral Carcinoma of the Ovary or Krukenberg Tumor (Carcinomes métastatiques bilatéraux des ovaires ou tumeurs de Krukenberg). *J. chir. Par.* 1937, p. 63.

This exhaustive study covers 165 cases of Krukenberg tumor which were published since 1927 including 6 of the author's own observation.

Although occurring at all ages, the tumor is most frequent in individuals between 30 and 40 years of age and comparatively rare in those past the menopause; therefore it seems that the functional activity of the ovary is a contributing factor to metastases into this organ.

The primary tumor could be ascertained in 139 of the 165 cases, either by operation or at autopsy. As to the clinical course four different types of tumor can be differentiated. The first found in about 50 per cent of the cases, present no gastrointestinal symptoms and their only sign is the increase of the abdominal volume, with or without amenorrhea. These cases are sometimes mistaken for pregnancy. In 3 instances torsion of the pedicle with severe pain, ascites, and hyperpyrexia led to the operation. In the second group including about a third of the cases the gastrointestinal symptoms were observed first and in the vast majority of the cases the stomach or the colon, especially the sigmoid was the site of the primary tumor. Two cases of this group were caused by a tumor of the appendix complicated by phlegmonous appendicitis. Only months or years after the surgery of these tumors were signs of metastasis in the ovary observed (increase of abdominal volume, amenorrhea, and sometimes neuralgias of sciatic type). In the third group (15%) signs of a mass in the lower abdomen coincided with signs of gastrointestinal disturbances so that the correct diagnosis was possible prior to laparotomy.

The fourth clinical group showed signs of generalized carcinomatosis, and only on the postmortem table was the invasion of the ovaries found.

Pathologic anatomy. Although in the vast majority of the cases the site of the primary tumor was in the digestive tract mostly in the stomach other locations, especially the mammary gland and the

uterus, may also be accompanied by bilateral metastases in the ovary. Among the 139 cases the primary tumor was found in the stomach in 95 cases, the small intestine in 2, the colon in 19, the appendix in 2, the pancreas in 3, the gall bladder in 2, the adrenal gland and the liver in 1 case each, the uterus in 5 cases and the mammary gland in 9 instances.

Histologically the Krukenberg tumor is characterized by pseudoglandular structures isolated elements, especially signet ring cells, and mixed pictures which some authors consider as transition structures. It is, however, no longer justifiable to distinguish between true and false Krukenberg tumors by depending on the presence of signet ring cells. The signet ring appearance is caused by accumulation of mucus in the cell which is characteristic of the carcinoma cell in general and may or may not occur in the ovarian metastases.

Very little is known of the pathogenesis. The question whether the Krukenberg tumor can occur as a primary tumor has for a long time been discussed in the literature. At present the consensus is that it is always a metastatic tumor although some cases have been published in which either the malignancy of the ovary seemed to precede a carcinoma of the gastrointestinal tract, or in which a true Krukenberg tumor was found as the only malignancy on post mortem examination and no primary tumor could be detected in the digestive tract or any other organ.

Another much discussed problem is the way in which the tumor cells invade the ovaries and the reasons for the special affinity of these organs to invading tumor cells. Since the experiments done by Krause, and later by Polano and Amann, the implantation theory has had the greatest number of followers. These investigators injected diluted Chinese ink intraperitoneally in guinea pigs, mice and dogs, and observed that the ink particles penetrated freely into the ovary.

The author criticizes this theory for various reasons. In the first place the implantation theory would demand that, to be implanted in the ovary, the cancer cells reach and ulcerate the serosa at the site of the primary tumor. It has, however, been demonstrated that in many cases the primary tumor in the stomach did not even reach the muscularis, much less involve the peritoneum. One cannot possibly imagine how in these cases, the tumor cells could have invaded the peritoneal cavity and reached the ovary in this way. Furthermore, exact histological investigations have never shown the presence of tumor cells at the surface of the ovary, rather the tumor originates in most cases from the central parts of the organ. In view of these facts, the author rejects the implantation theory.

He believes that the old theory of retrograde lymphatic invasion explains best the observed facts, and is supported by many detailed investigations. It has been shown in a great number of cases that the first invasion of carcinomatous cells occurred in the central part near the hilus of the ovary. Here the lymph vessels were filled with tumor cells which in-

filtrated into the surrounding tissue. This was observed also in cases in which the organ appeared normal macroscopically. The hypothesis of retrograde lymphatic infiltration would also explain the metastases from breast carcinoma to the ovary which cannot possibly be explained by the implantation theory.

Many hypotheses have been offered to explain the special predisposition of the ovary to develop metastases. Changes in the surface tension and in the pH may be contributory factors. Several men have observed that lowering of the surface tension stimulates and accelerates cell division. Extracts of malignant tumors have a lower surface tension than those of normal tissues. The same is true for the ovary and lymph nodes whereas the spleen and the muscles which rarely are sites of metastases have a higher than average surface tension. As to the pH it has been shown that the blood of carcinomatous patients has a more alkaline reaction than normal blood and that cancer cells grow much faster in an alkalized medium. On the other hand, the normal ovary and the lymph nodes have a slightly more alkaline reaction than the other tissues so it is conceivable that the tumor cells which circulate in the lymph stream are more apt to invade the ovary than other organs.

The prognosis is poor. Of 40 cases on record in which the primary tumor as well as the Krukenberg tumor in the ovary was removed, only 3 patients survived for more than 3 years.

WERNER M. SOLMATEL, M.D.

Holm Nielsen P: Injuries Caused by Hysterosalpingography *Acta obst. gyn. scand.*, 1946, 26: 565

The author reviews the recent literature as well as his experiences concerning the use of various iodized oils in roentgen visualization of the genital tract with particular reference to complications.

The most frequent complications are of an inflammatory nature, of which there are three main types: (1) recurrence of old adnexal inflammations, (2) primary adnexal inflammation following salpingography and (3) diffuse peritonitis resulting from the examination.

Of these the last 2 are of the most importance since they indicate infections produced by the examinations in previously normal individuals. In the patients in whom there is a flare-up of an old process there usually was noted a retention of the contrast medium in the tubes due to blocking of the distal ends. However, this does not mean that the inflammation is a result of irritation from the oil, more likely it is due to the manipulation associated with the examination. The absorption of oil from these tubes is very slow and evidence of its presence may be demonstrated for years. Also if the examination is carried out near the time of a menstrual period a flare-up may occur as ordinarily recurrences take place during or near such a period.

However, the incidence of inflammatory complications is difficult to ascertain. In two series of 300

Later abdominal distension, ascites and an extensive pelvic mass are found, accompanied by emaciation and cachexia. If a tubal lesion is thought of or suspected in an obese individual, examination under anesthesia, with preparation for immediate abdominal operation if a definite adnexal mass is found, is the procedure of choice.

The procedure should be complete abdominal hysterectomy with bilateral salpingo-oophorectomy rather than simple removal of the affected tube and/or ovary. Postoperative irradiation is indicated when operation has been, of necessity incomplete and the diagnosis of malignancy has been made in the laboratory or when metastases are observed. The question of irradiation therapy when operation has been complete, and when no metastases are visible, is debatable.

The prognosis of tubal sarcoma, as well as of tubal carcinoma, is doubtful at best. Curability can be enhanced only by early diagnosis and prompt treatment. The latter in the final analysis, can be made possible only by a keen appreciation of the symptoms and findings, but more probably by the periodic pelvic examination of women through continued lay and professional education. Meigs, J. V. and Ingersoll, F. M.: Thrombophlebitis and Phlebothrombosis in Gynecologic Patients: The Prophylaxis, Recognition and Treatment. *Am. J. Obst.* 1946 52: 938.

Because of the seriousness of embolism in cases of thrombophlebitis, a means was sought to prevent fatalities from this cause in postoperative patients. In the autopsy room, it was definitely shown that

nearly all fatal emboli come from the veins of the legs. The general plan of surgeons, urologists, and gynecologists of the Massachusetts General Hospital, Boston is to try to prevent pulmonary embolism whenever possible by ligating the proper veins in patients who have a suggestion of thrombophlebitis or phlebothrombosis and to interrupt definitely the femoral veins of those patients who have had a sublethal pulmonary embolus or infarct.

Diagnostic signs and symptoms indicating involvement of the leg veins and concomitant changes in pulse, temperature, and respiration, suggestive of a small unrecognized pulmonary infarct are presented. Various methods used in the attempt to prevent the formation of phlebitis or thrombosis in the legs of postoperative patients are discussed by the authors.

The details of surgical treatment are given the authors maintaining that both legs must be operated upon. Prophylactic interruption of veins is favored particularly in patients 60 years of age or older in which group most fatal emboli occur and especially in patients who have had phlebitis or an embolus following a previous operation.

There was no immediate mortality among 1,057 patients with vein interruption 75 of whom were gynecologic patients and except for an occasional lymphorrhea from the wound no serious complications have occurred.

Surgeons of the Massachusetts General Hospital are all convinced that interruption of the femoral veins is essential after a sublethal embolus or infarct. Nearly all are agreed that interruption of the femoral veins is essential after the diagnosis of thrombophlebitis and phlebothrombosis has been definitely made. JOHN R. WOLFF, M.D.

thus each cubic centimeter of the mixture contains 0.025 gm. of pentobarbital and 0.00006 gm. of scopalamine. When the patient begins to have regular pains at 4 to 5 minute intervals, which last for 30 or more seconds, the material is injected intravenously. An initial 3 to 4 c.c. are given at a rate of 1 c.c. every 5 to 10 seconds then it is slowed to 1 c.c. every 30 seconds until the patient falls asleep or talks incoherently. The average initial dose was 10 c.c. and the dosage varied from 6 to 20 c.c. Subsequent injections of about 2 c.c. are given when the patient becomes restless during contractions, does not sleep or becomes lucid between contractions.

Analysis of the results in 170 patients indicate that 89.4 per cent had complete amnesia while 10.6 per cent had partial amnesia. In 10.6 per cent of the patients there was some retardation of labor and in 2.9 per cent the contractions ceased completely. Three patients became unmanageable and required morphine in addition to the pentobarbital-scopolamine mixture. A severe fall in blood pressure occurred twice, and severe respiratory depression was noted once. One maternal death associated with cyanosis dyspnea, a fall in blood pressure, and a rise in pulse rate, occurred. Ninety two and four tenths per cent of the infants breathed spontaneously, 7.6 per cent required resuscitation and of these, 1 died.

The author believes that this is an efficient and safe method for obtaining satisfactory amnesia during labor.

Belvedere C.: Clinico-statistical Data and Observations on Podalic Birth in the Obstetrical and Gynecological Clinic of Bologna (Dati e rilievi clinico-statistici sul parto podalico nella Clinica Ostetrica e Ginecologica di Bologna) *Riv. Ital. Ginec.* 1945 18 150

The author reports on the podalic births occurring in the Maternity Clinic of the Obstetrical and Gynecological Hospital at Bologna for the 10 year period from January 1 1935 to December 31 1944. Seven hundred and forty-seven podalic births occurred among a total of 19 125 births during this period. Of the 747 infants 355 (47.52%) were males while 392 (52.48%) were females.

Of the mothers, 283 (38.71%) were primiparas under 30 years of age, 102 (13.95%) were primiparas over 30 years of age and 346 (47.33%) were multiparas.

In 633 cases the births were single births. In 99 cases, they were twin births. Among the twin births 32 (33.33%) of the mothers were primiparas and 67 (67.67%) were multiparas.

In 67 cases (67.67%) the fetuses were born one in cephalic presentation and one in podalic presentation and the fetus in the podalic presentation was born first in 24 of these cases (35.81%).

In 16 cases (16.16%) both fetuses were born in podalic presentation and in 16 cases (16.16%) one fetus was in podalic presentation and the other in shoulder presentation, and the fetus in podalic presentation was born first in 13 of these cases (81.25%).

Whenever the fetuses were in longitudinal position (cephalic-podalic presentation) the fetus in the cephalic position was most often born first. When the 2 fetuses were in the podalic presentation and shoulder presentation, respectively the fetus in podalic presentation was most often born first.

The course of pregnancy was perfectly normal in 578 (77.66%) of the mothers, while in the remaining mothers (169) it was complicated by some morbid condition. The morbid conditions complicating pregnancy were (1) conditions occurring in the mother independent of the pregnant state, (2) morbid conditions depending on the pregnant state, (3) anomalies manifest during the course of labor, and (4) anomalies of the fetus which caused difficulty at the time of labor. Of the diseases affecting the general condition of the mother, the most important were pulmonary tuberculosis (6 cases), the various cardiopathies (13 cases) diabetes mellitus (1 case) and lues (10 cases). Among the conditions resulting from the pregnant state there were the various nephropathies (48 cases) eclampsia (8 cases) and cystopyelonephritis (8 cases). Among the anomalies verified at the time of labor there were prolapse of the cord (19 cases) and placenta previa (8 cases). Among the complications caused by abnormalities of the mother there were contracted pelvis (30 cases) fibroma of the uterus (3 cases) deformity of the uterus (1 case) and polyhydramnios (3 cases).

Of the women with pulmonary tuberculosis (3 primiparas and 3 multiparas) 3 were delivered by podalic version the method of Krause, and 2 were delivered spontaneously in the last the pregnancy was interrupted at the seventh month by the method of Krause.

Of the women with cardiopathy (5 primiparas and 8 multiparas) 4 were delivered spontaneously and 5 by podalic version. In the remainder (4) the pregnancy was interrupted by the method of Krause.

Of the 8 women with eclampsia (7 primiparas and 1 multipara) 3 were delivered by cesarean section 2 by podalic version, and in 2 the pregnancy was interrupted by the method of Krause. Two of the women with eclampsia died immediately after delivery while a third one died on the fourth day of the puerperium.

Of the women with prolapse of the umbilical cord (4 primiparas and 15 multiparas) 17 were delivered by podalic version and 2 were delivered spontaneously.

Of the 4 women with central placenta previa and 4 with marginal placenta previa 2 were primiparas and 6 were multiparas. Two were delivered spontaneously 5 by podalic version and 1 was delivered by cesarean section.

Of the 30 women with contracted pelvis 10 were delivered spontaneously 11 by podalic version, 8 by cesarean section and 1 was delivered by craniotomy.

Presentation. Of the 747 fetuses in podalic presentation 117 were born in complete podalic presentation and 601 in incomplete podalic presentation in

The theory of resuscitation of the newborn is discussed in detail. The respiratory rhythm in extrauterine life, as it was formerly in intrauterine life, is cultivated essentially by chemical stimuli. After birth the bulbar centers of respiration are subjected to the influx of many afferent impulses, the most important of which act on the respiratory apparatus distention and retraction of the lungs and passage of air into the bronchial tree and originate in the carotid sinus (chemical stimuli which cause a variation in the composition of the blood). The fetus moreover comes to react to its surroundings (contact of air and temperature on the skin and mucosa, which leads to many reflexes on the neurorespiratory system).

The essential basis of the antiasphyxia treatment is the theory that a low oxygen tension in the blood stimulates the bulbar centers, while a further diminution of oxygen in the blood provokes a loss of excitability of the centers, the cells of which are very sensitive to the lack of oxygen. Oxygen determines the sensitivity of the neurorespiratory center, which then becomes capable of reacting to the specific stimulus carbonic acid. Anoxemia, which lasts for a certain time, represents a positive stimulus for the re-establishing of the center with oxygen, otherwise all the vital functions are destined to be extinguished. Only a further increase in the tension of carbonic acid can compensate for the time being for the lack of oxygen and overcome the elevation of the threshold of excitability of the center. The low oxygen tension and the high carbon dioxide tension of the blood which are constantly present in the last months of pregnancy and which in a degree maintain intrauterine respiratory rhythm, are not able to stimulate the bulbar centers after birth, as these centers become sluggish and insensitive in spite of a noteworthy increase in carbon dioxide tension. In this condition (oligopnea, or apnea, conservation of muscular tone, reflexes, and cyanosis) the spontaneous increase of carbon dioxide does not succeed in overcoming the excitability of the threshold of the centers; then, an increase of oxygen and eventually an increase of carbon dioxide occurs (according to Henderson the relations go to 10 for a short period of time and then it becomes 70 to 30). In this way cases of anoxemia of great seriousness and duration (apnea, loss of tone, absence of reflexes) are produced and only the immediate increase of oxygen can assure life of the newborn.

In 1938 the author performed autopsies on babies who had died from asphyxia directly after birth or a few days thereafter. His study revealed that in certain cases death was the result of improper treatment. The most common errors were

1. A tendency to proceed immediately with treatment without following certain indispensable preliminary measures, above all, without ascertaining whether the airways are completely unobstructed. Many babies were asphyxiated on account of the presence of meconium, amniotic fluid, blood, or mucus in the airways. No method of resuscitation would be successful unless the airways were unobstructed.

2. Utilization of brutal and inefficient methods of resuscitation.

3. Lack of respect for indications and contraindications for certain methods of treatment. Autopsies showed that apnea was accompanied by or provoked by hemorrhagic effusions, prematurity and interference with extrauterine respiration, oftentimes apnea was secondary to cerebral compression. In the condition of grave asphyxia, often energetic measures which are dangerous are employed. A method of resuscitation, such as that of Schnitzle, might be dangerous in babies with cerebral hemorrhage. All methods of manual artificial respiration used on babies which are nude and exposed to cold atmosphere might predispose to a rapid loss of body heat and produce shock in the newborn. On the other hand, hypodermic injection of stimulants when the peripheral circulation has practically stopped is useless and inefficient. Gaseous stimulation is useless when the pulmonary circulation is absent.

4. A tendency to neglect newborn babies after resuscitation has started.

From histological examination of tissues removed from the lungs of babies who were born asphyxiated, then resuscitated by artificial respiration, and subsequently died a few days after birth the author draws the following conclusions:

1. The frequency of large zones of atelectasis in the lungs of the newborn who died after a few days of life shows that it is not necessary for all pulmonary alveoli to be functioning in order to supply the necessary amount of oxygen for metabolism in the newborn. Only a moderate number are required. Methods of resuscitation should not produce hyperventilation of the lungs as this would be harmful to the child.

2. The physiological opening of the pulmonary alveoli is a gradual phenomenon which takes place slowly and is not reproduced artificially in a short time by means of forced endotracheal insufflation; neither is it produced by means of mechanical expansion of the chest obtained by producing highly elevated negative pressure. During insufflation the *vis a tergo* should correspond to a forced pressure of from 5 to 10 mm. of mercury and during mechanical respiration the negative pressure which should be exerted on the thoracic cage should not exceed that of a column of water of 10 c. c. in height.

3. Of the various methods of gaseous stimulation, the best are those in which the gaseous current is breathed by the newborn by active movement of its chest.

4. The procedures of artificial respiration which employ the more modern mechanical means ventilate the alveoli in a more physiological manner and are less harmful than rough manual methods.

A practical program of treatment for resuscitation. In general all apneic or asphyxiated babies should be protected against loss of body heat, dryness and overheating. All resuscitative measures which require the baby to be nude and which require the body temperature to be highly elevated, should not be used. The author considers the respiratory method

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Selye, H., and Stone, H.: Pathogenesis of the Cardiovascular and Renal Changes Which Usually Accompany Malignant Hypertension *J Urol* Balt., 1946 56 399

The literature in reference to renal hypertension is briefly reviewed with particular reference to the endocrine activity of the kidney. The authors constricted the aorta between the right and left renal arteries to cause the left kidney to become a function from a urinary secretory standpoint and along with tubular epithelial necrosis or degeneration the organ assumed the appearance of an endocrine gland. The authors found that this endocrine kidney although nonfunctional from a urinary standpoint, was apparently able to elicit the characteristic changes of hypertensive disease in the remaining cardiovascular system. This observation is contrary to the accepted views on the subject since it was thought that a kidney affecting such hypertensive changes must retain the power of urine formation.

The endocrine kidney was found to be responsive to pituitary extracts as demonstrated by cellular activity in the tubular epithelium and volume increase of the organ. Furthermore, the compensatory renal hypertrophy as occasioned by unilateral nephrectomy is inhibited by the endocrine kidney.

Partial constriction of one of the renal arteries was found to protect the affected kidney from nephrosclerosis either of renal or pituitary origin but the opposing kidney was afforded no protection. This finding it was felt, substantiated the belief that increased intravascular pressure was necessary to induce nephrosclerosis in animals.

Perarteritis nodosa was found cranial to the partially occlusive ligature of the aorta and could be induced in animals with anterior pituitary extracts which in addition produced corticoadrenal hypertrophy and hyperplasia. The adrenal vessels in this group frequently showed perarteritis nodosa, with necrosis in some instances this completely destroyed the adrenals except for a small layer of subcapsular cells.

The article is well illustrated and contains a comprehensive discussion and correlation of clinical hypertension in reference to the nephrosclerotic steroids, nephrosclerotic pituitary hormones, and renotropic hormones. ROBERT LEE, JR., M.D.

Sellinger H. and Sanberg, F.: Pyelocopy: An Evaluation of the Method *Acta radiol.*, Stockh., 1946, 27 617

Both intravenous and retrograde pyelography in certain cases leave both morphologic and dynamic facts undiscovered this is due to limitations inherent

in the method. The authors propose pyelocopy a combination of fluoroscopy with renal exposures to improve morphologic demonstration and functional mechanism demonstration. They use small spot films as in gastrointestinal roentgenography and have devised a method of keeping the end of the ureteral catheter sterile while it is being handled in the dark. A compression apparatus for the ureter devised by them, is also employed. In studying the phase of filling the tip of the catheter is inserted into the renal pelvis, just beyond the ureteropelvic junction. As soon as the pelvis has been adequately filled as seen fluoroscopically the catheter is withdrawn to L and the ureter then is filled. The patient is turned as required to demonstrate the entire caliceal system. For study of the morphologic details, the patient is turned and is also studied upright and during extremes of respiration. Fluoroscopic observation and simultaneous palpation is also used. The speed of emptying is then observed fluoroscopically.

Fluoroscopically controlled pelvis filling makes it possible to outline the pelvis before pain or tension, with its sequelae, are felt. When a ureter is kinked or looped on an ordinary film fluoroscopy will easily determine whether a respiratory movement or some similar physiologic effect has caused the ureteral distortion. Palpation during fluoroscopy will often demonstrate the relation of an abdominal tumor with the kidney. Pseudostrictures of the ureter are ruled out by fluoroscopy. When a hyperkinetic pelvis expels the dye during ordinary pyelographic filling, spot films taken at the very moment of filling will demonstrate the caliceal system easily. Lastly a vague defect in the pyelogram may prove to be a pseudopathologic finding and the fluoroscopic observation of the filling of the pelvis (pyelocopy) will demonstrate that the filling defect is purely functional.

The authors conclude that pyelocopy makes up for the shortcomings of intravenous and retrograde pyelography and believe that every retrograde filling should be performed routinely under fluoroscopic control. DAVID ROSENBLUM, M.D.

Begg, R. C.: Physiological Variations in Pyelograms Commonly Interpreted as Pathologic. *Brit J Urol.*, 1946 18 176

The author studied the physiological variations in pyelograms which were commonly interpreted as pathological. He stated that the ureters kidney pelves and calices pass through wide variations in form and position in accordance with bodily movement and posture, variable quantities of urine to be handled fluctuations in the pressure, and the resistance to overcome. Many variations observed in pyelograms, such as nephroptosis hydronephrosis ureteral dilatations, strictures and kinks are not pathological but are rather pictorial representations of

GENITOURINARY SURGERY

61

tion is unwise and usually futile. Heminephroureterectomy is the operation of choice in the average case and nephroureterectomy is favored when an entire kidney is damaged and the opposite one is normal.

When the segment of the kidney drained by the ectopic ureter is originally small has undergone atrophy and is not infected Everett recommends ligation and resection of the abdominal portion only. However if the ureter is dilated, as it usually is the stump may be the source of continued drainage and of very little additional surgery. Renal resection should always be done in conjunction with ureterectomy when feasible particularly when the anomalous segment is large functioning actively or is infected. In this patient the ureterectomy alone was warranted because of the risk of a heminephrectomy to the only remaining renal tissue.

JOHN A. LOXLEY, M.D.

Everidge, J., and Barnes, D. R.: Gunshot Wounds of the Ureter: 3 Cases, with Preservation of the Kidney in 2. *Bull J Urol* 1946 18 166

The authors have presented in detail 3 personal cases of trauma to the ureter sustained in warfare. They state that few cases of war trauma of the ureter have been recorded, probably because of the high mortality resulting from concomitant or associated injuries.

Clinically cases of ureteral injury present hematuria, either evidence of a urinary fistula which tends to appear in a week after the injury is sustained, or symptoms and signs of retroperitoneal abscess of a low grade infection. There is no significant early diagnostic picture of ureteral trauma. The early case could only be diagnosed by obstruction to the passage of a ureteral catheter or by surgical exploration. Excretory urography is equivocal and seldom justifies an immediate exploration.

ROBERT TURELL, M.D.

Davis, D. M.: Intubated Ureterotomy. *J Urol* Balt., 1947 57 233

A series of cases is presented in which ureteropelvic obstruction with resulting hydronephrosis was relieved by a procedure which the author terms intubated ureterotomy. The ureter was split longitudinally throughout the length of its narrowed portion and intubated with a gall bladder T tube (Fig 1). The narrow ribbon of ureter was held close to the T tube by a few sutures of 000 plain catgut. The T tube remained in place for approximately 4 weeks following the operation, in the main case cited and was then removed.

The author states that in no case in which this procedure was employed has there been a true failure. Symptoms have been relieved in every case. A residual urinary infection was present in 3 cases and subsided spontaneously in 3 years in 1 of the cases. All of the other cases were symptom free and showed sterile urine. The patient who has been followed up for the longest period of time shows a normal urinary

Fig 1 (Davis) Stenotic part of ureter incised for its entire length, T tube inserted, ureteral ribbon held in contact with T tube by a few sutures of fine plain catgut.

tract on the operative side 4 years and 3 months following surgery
CLARENCE V. HODGERS, M.D.

BLADDER, URETHRA, AND PENIS

Frather, G. C.: Spinal Cord Injuries: Care of the Bladder. *J Urol*, Balt., 1947 57 15

The author believes that the sequence of events in reference to the bladder following serious trauma to the spinal cord may be divided into three stages. The first is that of an atonic, neurogenic bladder. Cystometric studies at this time reveal a large capacity low pressure and no evidence of a reflex detrusor action. The second stage is that of an autonomic neurogenic bladder with periodic overflow incontinence. There is higher intravesical pressure and reflex contractions occur but are not sufficient to empty the organ. The third stage is characterized by micturition in patients with voluntary incontinence. It is characterized by complete transection of the bladder with an autonomic bladder with periodic involuntary emptying.

The author observed 130 patients with cord bladder who were treated during military service under the following regimen: drainage was provided by either a suprapubic tube or a urethral catheter and a closed system of drainage and irrigation was provided. Routine intravenous urograms were done and routine cystometric studies were deemed essential to determine the stage of bladder recovery and indicate when to institute voiding trials. When the patient's general condition was satisfactory and cystometric studies indicated the likelihood of successful voiding, the suprapubic tube was removed, a urethral catheter was inserted and the sinus allowed to close. Voiding trials were then instituted under close observation. Following this regimen in 21 cases of

mass extending upward from the upper pole of the epididymis, seemingly originating from either the cord or the epididymis. The tumor is characterized as a stony hard freely movable multilocular mass which may suggest a calcified varicocele and roentgen ray studies may confirm the presence of intra-tumor opacities.

Treatment indicated is operative exploration. Extratesticular masses may be benign in which case epididymectomy and excision of the tumor is indicated. In suspicious cases orchectomy should follow only the determination of neoplasia upon frozen section.

Grossly the tumor is a multiple fibroma and the characteristic microscopic picture is that of whorls of fibrous tissue with a few typical spheruloid vessel wall thickening with some areas of hyalinization and often calcification. The typical findings of chronic inflammation are routine. The tumors are referred to as multiple fibromata of the tunica vaginalis.

ROBERT LUCE, JR., M.D.

Kelby G. M., and Stenstrom, K. W. The Treatment of Malignant Tumors of the Testis. Review of 100 Cases. *Radiology* 1947 48 1

A study of 100 testicular tumors treated at the University of Minnesota Hospitals, Minneapolis from 1936 to 1934 is reported. Thirty four were not classified as to type 37 were seminomas and 29 were carcinomatous mixed tumors according to E. T.

Metastases were present in 86 per cent of the cases at the start of irradiation treatment.

Bell's classification. The average age of the patients with seminoma was 37.6 years and of those with carcinomatous mixed tumor 39.4 years. A history of trauma was obtained in 15 per cent of the cases. Cryptorchidism was present in 8 patients and hydrocele in 6.

The treatment consisted of simple orchectomy followed by irradiation immediately whenever possible. However, the average time interval between operation and irradiation was 3.5 months. Cases without demonstrable metastases received about 3,000 r in air in fractionated doses to an anterior and posterior abdominal portal each over a period of 3 weeks. If a large abdominal mass was present intense treatment was at first directed to it. Other areas were irradiated thereafter if a local response had occurred. Six advanced cases were irradiated only, whereas 4 cases were subjected to Hinman's dissection (a more radical operation) which was followed by radiation treatment.

The results are shown in Tables I, II, and III.

The authors arrived at the following conclusions:
1. Tumor of the testis is frequently found in patients with hydrocele.

is particularly prone to occur if the capsular ligament is cut and subsequently sutured. In a dissection of several cadavers the author discovered a thick ligamentous structure which is the capsular ligament of the distal radioulnar joint lying just under the tendon of the extensor digiti quinti proprii. The capsular ligament of the distal radioulnar joint is tightest on the dorsal aspect during pronation, and is tightest on the volar surface in supination. From this it was concluded that it was advisable to immobilize the forearm in a plaster of Paris bandage in the neutral position, which is the position in which the ligament is relaxed.

These conclusions were based on the study of a 26 year old white female who sustained an injury to the left wrist when she struck her limb on the edge of a machine in a hat factory. Subsequently a mass developed on the dorsal and inner aspects of the left wrist. An x ray film was taken and it was reported to be negative. The swelling was diagnosed as a double ganglion and it was excised under general anesthesia. A plaster of Paris cast was applied for a period of 2 weeks.

Examination some 6 months later indicated that the patient had a pronation contracture of the forearm and that active supination was impossible. A dimpling of the skin at a point corresponding to the dorsum of the distal radioulnar joint was noted when supination was forced with the patient under anesthesia. This band could be palpated. By forceful manipulation an audible snap was heard and the contracting band disappeared. However complete supination could not be obtained until a scalpel had been introduced between the ulna and the skin at the site of the scar and the band had been divided. Months after the operation there was still about 20 per cent loss in active supination.

C. FRED GORRINGER, M.D.

Allen, I. M.: Atrophy of the Outer or Radial Side of the Thenar Eminence; A Benign Disorder. *N Zealand M J* 1946 45 549.

The author presents a series of cases of benign atrophy of the radial portion of the thenar eminence. In every case there was a partial, sometimes sharply defined atrophy of the radial portion of the thenar eminence. In many cases the muscles of that part had diminished to such a degree that the radial edge of the first metacarpal bone, especially at its base, was visible and easily palpable. From inspection and palpation the impression was that the muscles involved were the abductor pollicis brevis and the opponens brevis.

In a study of the nerve supply to these muscles Saunders found that the branches of the median nerve ran a highly recurrent course from its origin beneath the transverse carpal ligament. In some cases, separate branches ran to the abductor pollicis and to the opponens pollicis. In other cases the nerve occupied (for part of its course) an unprotected position just beneath the skin, where it was exposed to trauma which is possibly an important factor in

the production of the syndrome. Other cases of atrophy, without a history of injury, may be explained by the possibility of a frank polyneuritis. In some cases there is evidence to show that the affected portion of the thenar eminence and its nerve supply may be prone to a developmental defect.

The author made a study of the essential features of 11 of the 23 cases which he investigated.

C. FRED GORRINGER, M.D.

Gurl, J. P.: The Formation and Significance of Vertebral Ankylosis in Tuberculous Spines. *J Bone Surg* 1947 29 136.

Tuberculosis of the spine cannot be said to be healed until there is a fusion of the affected bodies. When ankylosis has occurred recurrence of the disease and increase in the deformity are not observed. The most rapid formation of vertebral ankyloses occurs in cases with circumscribed foci localized near the margin of the vertebral bodies (average time 1 1/2 years after onset of the symptoms). Cases presenting destruction in the paravertebral areas ankylosed in 3 or 4 years. In cases characterized by progressive thinning of the intervertebral space fibrous union was obtained in 4 or 5 years.

The formation of a vertebral block composed of two or more vertebral bodies is influenced in speed and type of formation by the segment of spine involved (cervical, thoracic, lumbar).

When the disease process involves the center of the vertebral bodies loss of the intervertebral joint space occurs rapidly.

Spinal fusion prior to formation of a sound vertebral block of the anterior spine does not prevent further deformity or spread of the disease.

Body ankylosis may not be obtained in children even after very prolonged periods of treatment with or without a spinal fusion.

VERNON C. TURNER, M.D.

SURGERY OF THE BONES JOINTS, MUSCLES, TENDONS, ETC.

Kelly, R. P.: Skin Grafting in the Treatment of Osteomyelitic War Wounds. *J Bone Surg* 1946 28 681.

In some war wounds loss of both bone and soft tissue is so extensive as to preclude secondary closure, and some other means must be sought for inducing prompt healing. Free skin grafts will often effect healing in such wounds. There is little basic difference between closure by skin grafts, either free or pedicled, and secondary or primary closure.

Saucrization is a procedure which involves removal of all dead or devitalized tissue, and the contour of the wound is so arranged that application of appropriate pressure to a skin graft will be possible.

Usually a free graft is applied to the saucerized wound as a temporary measure. It is best done about 4 days after saucerization, but grafts may be applied at the time of this operation or as long as 6 weeks later. The receptiveness of the bed for grafts

and subsequent joint function was impaired beyond what would have been expected from the wound damage. In some cases in which the bone and joint damage was not extensive, there was lingering sepsis and slow joint destruction. In cases in which there was extensive bone and cartilage destruction by the original trauma, severe septic arthritis was the rule. Fortunately only a few amputations were necessary but the joints were permanently destroyed.

The program which was laid down in 1944 for the management of all knee joint wounds, penetrating or perforating, regardless of the time which had elapsed since the wound was received, was as follows:

In the forward area, after preparation by transfusion of blood or plasma, the joint was thoroughly opened, and foreign bodies and other material were removed. Loose bone chips, loose cartilage, and damaged menisci were excised. Defects in condyles were trimmed evenly and comminuted patellae were usually removed. The joint cavity was thoroughly irrigated. The synovial membrane, and at times the capsule, was closed, and 10,000 to 20,000 units of penicillin were instilled into the joint. When insufficient soft tissue remained to close the joint, a skin or fascia flap was mobilized to cover the defect. If damage was so extensive that closure could not be achieved, and the joint was considered hopeless, excision of the remaining joint cartilage was advisable. Immobilization was accomplished by a single hip spica or a Tobruk splint. Systemic penicillin was continued. From 24 to 48 hours following the surgery the joint was aspirated and irrigated, and filled with penicillin by means of a large needle.

In the base hospital, 4 to 6 days after the wound had been received, reparative surgery was done. The joint was again aspirated, irrigated, and filled with penicillin, and the remaining open wound was closed. If doubt existed as to the proper treatment in the forward area, the joint was reopened and examined.

In 10 to 14 days after the wound had been sutured, immobilization was discontinued and active motion begun, with the limb in balanced suspension in a Thomas splint with the Pearson attachment. Signs of sepsis within the joint were treated either by reoperation with thorough cleansing of the dead tissue and blood clots, or were repeatedly aspirated, irrigated, and filled with penicillin.

If hope of a functioning joint had to be abandoned, radical resection of the joint was preferable to open drainage.

Hampton presents data from several series of cases to show the marked improvement in results when this program was followed. In one large series the incidence of sepsis dropped from 7.4 to 5.1 per cent. Eight very interesting and convincing cases are presented in detail, with roentgenograms and photographs.

Among the conclusions drawn by the author is the decision that continuous drainage of fluid from the knee joints is not adequate surgical treatment in cases of suppurative arthritis and is not indicated. He believes that knee-joint resection has a definite place

in the management of severe wounds and sepsis in military surgery
NEWTON C. MIKIN, M.D.

Ottolenghi, C. E. and Del Sol, J. M.: Anterior Arthrodesis of the Instep (*La artrodesis anterior de la gárganta del pie*). *Rev. A. med. argent.*, 945, 60-630.

Anterior arthrodesis of the instep is a simple procedure and when done with the correct technique, satisfactory results are assured.

The author reports 53 such operations. The indications included (1) alteration of form because of deformity from traumatic, infectious gonorrheal, or tuberculous arthritis, or fractures of the malleolus, astragalus, or the leg. (2) alteration of function because of central or peripheral paralysis, such as from poliomyelitis, or from paralysis of the sciatic nerve or some of its branches.

The arrangement of the graft is either intra-articular para-articular or extra-articular for slipping, with or without resection of the articular surface or for inversion.

STEPHEN A. ZIEGLER, M.D.

Gul, L.: Disarticulation of the Transmetatarsal Joint of the Lisfranc Type (*La disarticulación transmetatarsiana de Lisfranc*). *Chir. org. modica*, 946 30-2.

The author reports 373 disarticulations of the transmetatarsal joint in a total of 300 patients which were done in a period of 31 months, from April 1941 to January 1944.

The Lisfranc amputation has fallen into some disrepute in the past because of the fact that the muscle balance was disturbed, the patient no longer walked well, and before long he developed pressure sores where abnormal weight bearing occurred.

The technique used in the 373 cases was a modification of the Lisfranc operation perfected by Scaglietti. This modification consisted of transplanting the tibialis anterior tendon and the extensor hallucis longus tendon into the center of the disarticulation so that a movement of extension could be made and any movement of supination of the foot could be prevented, and a slight amount of pronation of the foot would be produced so that the whole plantar surface of the extremity would come in contact with the ground on weight bearing.

The large number of cases were the result primarily of frostbite during mountainous warfare. The operative procedure recommended by the author is the removal of the cartilaginous portion of the distal tarsal bones and then smoothing down the bones well by the use of a file so that there are no rough protruding spicules of bone. Then the tibialis anticus and the extensor hallucis longus tendon are firmly sutured between the second and third cuneiform bone with the tendon of the peroneus longus. This gives a good stable attachment and the foot can be brought into direct contact with the ground in walking. The inability to do this has been the one great criticism of the Lisfranc operation in the past. The plantar skin and subcutaneous tissues are utilized so

that no weight is placed on the thin dorsal skin and subcutaneous tissues. The suture line is always made on the dorsal surface of the foot.

Postoperatively the author recommends the insertion of a drain for a short period of time and the immobilization of the extremity in a plaster cast which extends from the middle third of the thigh down to the tip of the foot with the knee bent to 25 degrees and the foot at a right angle with a slight amount of pronation.

In this series of cases there was 1 death from a pulmonary embolus. In 5 patients with postoperative hemorrhage another operation with ligation of the bleeding vessels was necessary.

CARLO SCUDERI, M.D.

FRACTURES AND DISLOCATIONS

Sulzer, P. and Thobols, P.: The Treatment of Fractures of the Clavicle by Internal Splinting with Kirschner Wire (Sur l'embrochage par broche de Kirschner dans le traitement des fractures de la clavicule). *Lyon chir.*, 1946 41: 552

There are numerous methods used for the repair of fractures of the clavicle with displacement but none is entirely satisfactory. All of them make daily inspection of the position of the fragments and of the condition of the apparatus necessary. This is difficult in a hospital and nearly impossible in private practice. It is hard to immobilize the shoulder and sternoclavicular joints and there is danger of compression of the nerves and vessels in the axilla. None of the appliances thus far devised are comfortable nor do they preserve reduction of the fragments of the clavicle.

Internal splinting makes all of these considerations unnecessary. It maintains reduction by giving the bone its natural curve. This is also true in multiple fractures of the clavicle. The wire is firmly anchored in the principal fragments.

This procedure is based on the work of Kuntschner in the intramedullary nailing of long bones. However, the conditions encountered in pinning of the clavicle are somewhat different from those encountered in nailing of the bones of the extremities. The clavicle is cancellous on the medial and lateral ends therefore the pinning is intramedullary only in the midportion of the bone. The location of the skin incision also presents a problem different from that in nailing of the bones of the arms and legs. Goddard does not use any incision at all. Rocher states that manual external reduction is unsatisfactory and that an incision is necessary. Sicaud uses an incision only in multiple fractures of the clavicle. Pinning of the clavicle under constant x ray control so easily done in the extremities, is impossible because the clavicle cannot be viewed from various angles by means of x rays. This is one important reason why an incision is necessary. Fractures of the clavicle are often badly displaced, and reduction by external means alone is very difficult. Even in the absence of severe displacement, reduction of fractures of the lateral

portion of the clavicle by using the arm as a lever is impossible because of the conoid and trapezoid ligaments. Often the roentgenogram fails to reveal all the fragments in a severely comminuted fracture. Manipulation often causes the skin over the clavicle to be pierced by one of the sharp obscure fragments.

It is also important to protect the underlying large vessels and nerves and much safer to make an incision and discard all esthetic objections.

The technique of pinning has to be adjusted to the site of the fracture. Rocher inserts the Kirschner wire through a prepared opening at the medial end of the clavicle. The clavicle has the shape of an S. It seems to be very difficult to predetermine the direction of the opening at the medial end of the clavicle for every type of fracture of the clavicle. If the opening is incorrect the wire abuts against the inner wall of the cortex and does not enter the lateral fragment. Also the wire may slide along the inner wall of the cortex and impact against the outer fragment.

Insertion of the wire through the dorsal aspect of the clavicle seems to be the best method. The Kirschner wire inserted through a small skin incision should enter the outer fragment in cases of fracture of the medial third and in certain fractures of the middle third of the clavicle. It should enter the medial fragment in fractures of the outer third and in most fractures of the middle third.

Descriptions and diagrams are presented to illustrate a few technical details in 3 typical fractures of the clavicle.

The patient is generally allowed to move his shoulder and elbow on the next day. The wire is removed on the twenty fifth day.

The author states that he found that fractures of the clavicle treated with internal fixation heal more slowly than those treated by manipulation and external immobilization. No explanation of this observation is offered. It is suggested that the play which the fragments have around the wire or the presence of a foreign body may be responsible for the slow union.

GEORGE I. REISS, M.D.

Hauser, E. D. W.: Special Techniques for Unusual Fractures of the Forearm. *Q. Bull. Northwest. Univ. M. School* 1947 21: 18

The author presents a number of cases of difficult fractures of the forearm illustrating the principles of treatment with varied techniques.

In compound fractures, in addition to the usual methods employed in cleansing the skin and the wound itself, he used emulso, a cationic detergent, to cleanse the skin, and repeatedly washed the wound with a 1:3,000 aqueous solution of zephiran chloride.

When malunion could be corrected by osteotomy he used drill openings connected with an osteotome until the bone could be bent. In other words the result was similar to that when the brushes of two brooms interlock.

The author's fourth case presents an interesting problem. The patient was an 8 year old child who

had a marked ulnar deviation of the hand, caused by cessation or at least, a slowing down of growth at the distal ulnar epiphysis following the application of radium to a strawberry nevus at the wrist at the age of a year. The distal ulna, including the cartilaginous epiphysis which contains two centers of ossification, was split longitudinally and a tibial graft was wedged in place in the cleft. Union occurred and led to correction of the ulnar deviation of the hand.

The author prefers external fixation of compound fractures when possible, but was forced to use plates at times.

VANNOY C. TUCKER, M.D.

Howorth, M. B.: Congenital Dislocation of the Hip. *Ann. Surg.* 947 125 216.

The cause of congenital dislocation of the hip is still vague. Both the anatomical and embryological explanations have been few and far between. The authors have made an extensive study on 15 normal fetuses of which the ages ranged from 10 weeks to full term. Dissections, roentgenograms and serial sections were made to make a comparative analysis of the embryological anatomy of the fetuses 10 weeks, 3, 4, 5 and 6 months old, respectively. The lengths of the femurs varied between 3 and 8 cm.

The youngest femoral specimen (10 weeks old) measured 3 cm. The muscles and tendons of the hip and thigh were not differentiated from each other. Rather than an individual muscle, one observed a pale homogeneous mass. However the gross appearance of the capsule, and the femoral and acetabular articulation was comparable to that of a fully developed fetus or adult hip. The femoral head and acetabulum measured 5 mm. in diameter and were covered by cartilage. The capsular apparatus was well developed and provided firm stability to the hip joint. The angle between the neck and shaft of the femur averaged 140 degrees.

All of the hips in fetuses 3 months old or older disclosed a similar developmental pattern. Muscles differentiated from each other blood vessels and nerves were discernible, and there was a normal cartilaginous lip along the posterosuperior half of the margin of the acetabulum. With the exception of limited 145 degree motion in extension, the function of the thigh approached normal values.

In another group of hips (8) studied by the author the only variations worthy of note were that (1) the tendons could be distinguished from their muscles, (2) the thigh extension was limited to 160 degrees, (3) the labrum glenoidale was well developed, and (4) the habenarian gland was well developed.

Despite the splendid research work done by the author no appreciable advance in our knowledge concerning congenital dislocation of the hip has emanated from this study. For instance, nothing has been learned relative to its great preponderance in the female. Workers at the Rockefeller Institute are alleged to have observed congenital dislocation in rabbits it is hereditary in this species and can be inbred.

The author's study is based on 385 cases of congenital hips. His findings were as follows

In all but a few cases the femoral head was dislocated outward, upward and forward, with the capsule and rectus tendon greatly elongated the capsular apparatus was thickened. Contrary to the text book dicta, the capsule was not always hourglass in shape. There was uniform limited adduction, due mostly to contraction of the adductor muscle. The posterior dislocation of the hip was limited to the older group of patients. Because of muscle contraction (anterolateral group) with adherence of the capsule to the ilium and flattening of the anterior acetabular hip margin, much resistance was offered in telescoping the hip from the ilium. The gracilis and adductor longus were the principal offenders. The remaining adductors and the hamstring group of muscles rarely participated in the immobility of the congenital hip. The acetabulum was not only shallow but was generally occupied by the habenarian gland, which in the majority of cases would prevent reposition of the femoral head unless the surgeon gouged out the copious acetabular debris. It was further noted that the habenarian gland often replaced the acetabular cartilage as a fibrous obliterated mass. The ligamentum teres was elongated, hypertrophied, frayed, or absent.

In half the cases the acetabulum was not deep enough to accommodate the femoral head. In a smaller percentage of cases, the head was much greater than the acetabulum. Some of the heads were flattened medially which precluded adequate reduction without surgical interference.

Closed reduction is the treatment of choice in infants under a year of age. The traumatizing procedure of Lorenz should be abandoned. The Hibbs procedure, according to the author is far more advantageous. Immobilization to 90 degrees of flexion and adduction is recommended for from 3 to 6 months. Walking is permitted 2 months after the completion of reduction.

Preliminary skeletal traction combined with tenotomy of the gracilis and the adductor longus is far superior to the brutal tearing of such muscles in the older group of children. Open reduction, in capable hands, is the treatment of choice in the older group.

The author prefers a Smith-Petersen type of incision. The capsule is incised anteriorly, but cutting it superiorly is avoided. The hypertrophied habenarian gland and fibrous tissue is gouged out from the acetabulum. Any adhesions between the capsule and ilium are released. Correction of the antversion is sometimes indicated. It can be obtained by supracondylar transverse osteotomy. Immobilization in a plaster of Paris cast for 6 weeks is recommended, care being taken not to precipitate a coxa plana.

Shell stabilization is reserved for children over 10 years of age or older. The procedure advocated is the Gill method, which has been extremely efficacious in the irreducible congenital dislocations. Here, too, preliminary traction is of paramount importance.

Cup arthroplasty is indicated for bilateral hip arthropathies and fusion may be performed in the unilateral and painful arthropathies.

SAMUEL L. GOVERALE, M.D.

Bosworth, D. M.: Fracture Dislocation of the Ankle with Fixed Displacement of the Fibula Behind the Tibia. *J. Bone Surg.* 1947 29 130.

Attention is called to a condition fracture dislocation of the ankle joint which probably has escaped recognition by most surgeons. Five cases are presented in which a posterior displacement of the proximal fragment of the fibula behind the tibia prevented accurate closed reduction. Open reduction requires the use of a pry pin between the tibia and fibula and the use of considerable force to snap the fibula back into normal position. Following this anatomical reduction of the ankle has been easy pulled back behind the tibia by the intact fibula is ligaments. Continuation of the force rotating the talus backward and out from its position beneath the tibia causes further force on the collateral ligaments and, finally, the fibula is broken off against the posterior tibial border. With this fracture there is nothing left attached to the upper fragment with which it can be pulled back into place.

Most ankle fractures do not have a posterior displacement of the fibular shaft because the malleolus is broken by pressure against the lateral surface of the tibia.

The diagnosis of posterior fixation of the fibula by means of roentgenograms may be missed since one may believe that the view taken is not truly lateral. In a true lateral view the fibula does not lie posteriorly but is superimposed on the center of the tibia.

UNKNOWN C. TURNER, M.D.

Magee, R. K.: The Kuntscher Method of Pin Fixation. *Canad. M. Ass. J.* 1947 56 65

The Kuntscher method of pin fixation was popularized by its use at the Kiel German Naval Hospital and was first reported in March 1940.

The author studied 20 cases in which this method was used, at the Clinic of Professor J. F. Nuboer in Utrecht, Netherlands. The principle is the same as that of the Smith-Petersen pin fixation for femoral neck fractures, i.e. axial intramedullary fixation, by large cannulated stainless steel rods of fractures of shafts of the long bones. The pins range from 7 to 11 millimeters in diameter and vary in length. The width of the medullary canal is measured by means of a roentgenogram of the bone taken at a distance of one meter from the x-ray tube. The next smaller pin is used so that it can be inserted more readily and yet held firmly. The longitudinal fluting prevents rotation. Pins for femurs are straight, those for tibiae are slightly curved and have split flared lower ends to engage in the wide lower tibial medulla. Pins and other instruments are illustrated, as well as a patient prepared side lying on a Hawley table.

The ideal case for this procedure is a transverse fracture of the mid-shaft or of the upper one third of the femur or the upper half of the tibia. The technique of a femoral pin insertion by the closed and open method is described in detail. Closed reduction is carried out under strict fluoroscopic control. Epi-

dural block anesthesia is preferred in Professor N. N. boer's Clinic. There was no shock at all in the cases observed. No external fixation was used for femurs. Active motion of the knee and of the hip is encouraged in 2 or 3 days after surgery. Patients with transverse fractures are up on crutches in 2 to 3 weeks, and patients with other types of fracture are up when x-rays show adequate callus.

Unusually large fusiform callus is often demonstrable in roentgenogram, in 2 to 3 weeks. Whether impaction or the extrusion of marrow substance into the fracture site is responsible for this response is not known. Pins are removed in from 3 to 4 months, or later in cases of pseudarthrosis.

The tibial pin is inserted through an oblique window in the upper inner cortex and the pins flare on the lower end to hold in the widened distal medullary canal. A plaster cast from groin to toes is used to prevent rotation. The method has been used for fractures of the humerus, ulna and radius.

Several cases are presented with roentgenograms. All patients were young adults in whom rapid solid union was obtained. The first case in America in which the Kuntscher method was used is described.

Even in open reduction there is little disturbance of the soft tissues, as periosteal stripping is avoided. Infection is not likely if compound fractures are not included as in the group studied, the procedure was carried out without the protection of penicillin. Occasionally a pin may break or a ring sequester may develop. The exposure to radiation of the assistant who reduces the fracture under fluoroscopic control is a hazard. The technique is detailed and demands facilities and teamwork available only in a fracture center but has advantages over other methods in upper femoral fractures.

FRANCIS E. BREDENECKE, M.D.

ORTHOPEDICS IN GENERAL

Zawisch, G.: Marble Bone Disease; A Study of Osteogenesis. *Arch. Path. Clin.* 1947 43 55

Marble bone disease is commonly known as Albers-Schoenberg disease osteopetrosis, or osteosclerosis fragilis generalisata. The disease is due to the influence of an unknown agent which damages the bone forming blastema at the beginning of the second period of development of each bone. From this time on the differentiation of bone tissue is retarded and the less differentiated types become hyperblastic. The malformation is responsible for the general retardation of resorption because the two phases of the bone forming process—deposition and resorption—stimulate each other.

The basis for the author's study was an infant, 11 months old. Detailed description of the microscopic findings is given which outlines the findings in the various periods of bone growth. From this it was concluded that in marble bone disease the threshold of response to stimuli which bring about resorption is raised. Resorption is arrested at the beginning of the second period for a long time. The results are the

Fig. 2 (Zawisch) Marble bone rib, part of a longitudinal section. Note the epiphyseal line and the densely packed spongiosa. To the left, cortex and periosteum. Azan-Mallory stain, X350.

fetal size and shape of the marrow cavity a thick cortex composed of all the embryonic strata which normally are removed, and an unusual amount of spongiosa. In the finer histologic structures it was found that the osteoblasts everywhere were so flat that they were hardly distinguishable.

Despite conflicting statements in the literature it was the feeling of the author that osteoclasts are present in all stages of their evolution. The absorption front of the cartilage is normal, but the succeeding endochondral ossification is pathological from the beginning. Normally the first period stage, in which no endochondral bone is formed, is being repeated as long as the bone grows. The capillaries which absorb the cartilage always keep ahead of the osteoblasts, and deposition of bone begins at a certain distance from the absorption front. Thus, the capillaries have time to absorb a certain amount of cartilaginous ground substance. As soon as a cartilage cell is liberated by the absorption of its walls, basophilic matter and an osseous globule are deposited in the cavity.

Endosteal ossification in marble bone disease shows the same pathologic development as cortical ossification. A hyperplastic production of less differentiated bone tissue, containing more basophilic matter than usual, is at the root of the evil.

There is no doubt that many patients with marble bone disease show recessive heredity but others do not.

Clubbing of the ends of long bones is the result of the hyperplasia and persistence of less differentiated types of bone tissue in the metaphyses. These metaphyses which grow most rapidly are more readily affected. Histochemical methods have not been used up to now and the general ash contents have not been analyzed except by Clifton, Frank, and Freeman, who made use of a biopsy fragment for this

purpose. They showed that the spongiosa has a higher ash content than the cortex. Those types of tissue e.g., chondroid bone and the basophilic inclusions, which even normally do not contain fibrils, are hyperplastic in marble bones and this increases the absolute amount of calcium. The spongiosa is richer in basophilic inclusions than the compacta. The greater density of marble bones in the roentgenogram is due partly to a greater density of structure when the bones are in a state of repair (eburnation) and partly to a higher calcium content, revealed indirectly by the scarcity of fibrils in all the types of bone tissue involved.

Polarized light reveals a relative scarcity of fibrils in all the bone tissues. Chondroid bone of the type which is hyperplastic in marble bone does not contain fibrils even normally and the pathologic change in the ground substance consists merely in an increase of basophilic. In the other bone tissues the scarcity of fibrils is very conspicuous. The anemia in marble bone disease may be due to the same agent which impairs the differentiation of bone tissue.

C. FRED GORMAN, M.D.

Copeman, W. S. C. and Ackerman, W. L.: Edema or Herniations of Fat Lobules as a Cause of Lumbar and Gluteal "Fibrositis." *Arch. Int. Med.* 1947 79 22.

Edema, herniation, and strangulation of fat lobules are postulated by the authors as the true cause of fibrositis, or painful back. Biopsy material has not substantiated any pathologic evidence that fibrositis exists *per se*. On the other hand, each of the 11 cases presented exhibited fibrofatty deposits at the painful point and extirpation resulted in an apparent cure of the syndrome.

The authors' classification of the herniated fatty tumors is as follows: (1) pedunculated, (2) non-pedunculated, and (3) the foraminal type. The last develops from one of the three segmental lumbar nerves or vessels. All tumoractions can become severely compressed or contused (by trauma) between the deep and superficial lumbosacral and gluteal fascia. Demonstrable hyperemia coupled with edema of the excised tumor has convinced the authors that they are dealing with a definite clinical entity which in their experience, when subjected to surgery, was permanently cured.

Furthermore, it is to be remembered that whereas these tumors have been treated heretofore by novocaine injection, the cure has been questionable. It is true that the fat tumor is accompanied by nerve trunk, injections will not relieve the pressure.

Interestingly enough, the surgical approach is performed under local block. Digital pressure is exerted on the herniated fat tumor until the patient involuntarily winces (trigger point pain). The offending mass is not removed alone, but all surrounding fat disintegrated by destruction of its septae.

In the brief period of postoperative observation it was noted that no recurrences had appeared in any of the 11 cases.

The authors have also studied and dissected 24
ordervers
SAMUEL L. GOVERNALL, M.D.

Kessler H. H.: Rehabilitation of the Arm Ampu-
tee. *Plast Reconstr Surg* 1947 3 1

During the 4 years of World War II 17 000 service men lost their limbs as a result of war wounds and operative injuries. During the same period 150,000 civilians lost their limbs from accidental injuries and disease. Of both groups approximately a third were arm amputees.

There are two primary requirements that a prosthesis must fulfill if it is to meet the needs of an arm amputee: that of dress and that of utility for the routine pursuits of life. To date there has been no one prosthetic device that satisfies these requirements. The functions of the upper extremity are so intricate and complex that they cannot be duplicated; they can only be imitated. Furthermore the one function that the amputee misses above all else is tactile sensation.

In a survey of 9,000 arm amputees in Germany 60 per cent preferred the arm prosthesis for dress alone. Made of wood, leather, plastic, latex, or felt, it can be made comparatively light, and in some cases even sufficiently artistic to duplicate the natural appearance of the normal hand.

It is impossible to duplicate the combinations of hand and finger function. However, there are four simple functions which are important and can be duplicated mechanically. They are forceps action, pliers action, ring action and hook action. These functions can be obtained by the standard type of utility hook which is held closed by a heavy rubber band and opened by the action of a loop around the opposite shoulder which pulls on a lanyard attached to an outrigger on the hook. Closure of the hook is accomplished by the simple release of the pull on the lanyard, the hook closing by the action of the elastic band. While the amputee can exercise considerable ability in the handling of routine tasks, the hook does not hold soft objects such as a cigarette or a doughnut, satisfactorily.

In the cineplastic procedure the muscles that remain in the stump are canalized and attached to a system of levers so that the flexors and extensors in the forearm and the biceps and triceps in the upper arm activate the artificial hand and arm. The great advantage of this method is the natural and physiological action, the simplicity of the mechanical device, the effortless control and the avoidance of straps, loops and harness to the opposite shoulder for below the elbow arms. However the principle had its limitations in application to the needs of factory workers, farmers and laborers who required a prosthesis that could exercise considerable force.

The scope of cineplasty can now be extended to more varied and energetic physical demands through the development of a utility hook operated by cineplastic motors and interchangeable with a cineplastic hand. This has been accomplished by the development of an ingenious spring coupling which permits

Fig. 1 (Kessler) Cineplastic prosthesis for upper arm amputee.

interchangeable action of the band and hook by the cineplastic motors.

In addition to cineplasty other special methods are available to the amputee to meet his special needs. The Krukenberg operation is one of these methods. It consists of the splitting of the forearm into two fingers so that the approximation of the two digits provides prehension while the natural skin innervation permits normal tactile sensation. The method has been very popular in Germany and Russia. In the United States where public prejudice exists toward the appearance of the stump there has been a natural reluctance to undertake this measure. It is a valuable procedure for the bilateral amputee since he requires no prosthesis. It is of especial value for the blind bilateral arm amputee.

In the rehabilitation of the arm amputee a five point program is required: the psychological preparation of the patient, the selection of adequate surgical methods which will give him a painless and satisfactory stump, the aftercare of the stump, the selection of the device or special surgical procedure which will permit him to wear a prosthesis and finally the training of the amputee in the use of the prosthesis.

C. FRED GOVERNALL, M.D.

Mislove, R. K.: Sauerbruch Cineplastic Amputation.
Lancet Lond., 1946 2 904.

The author indicates that the cineplastic amputation as developed by Sauerbruch appears to have the advantage of permitting more dexterous movements under more normal muscle control than the usual prosthesis. Amputees at Sauerbruch's clinic demonstrated that they could write with normal legibility and could pick up a map with forceps or with the hand, pick out a cigarette and light it, and attend to their clothes. This type of amputation is applicable only to the upper limb and is best chosen for bilateral cases. The shortest stump in the forearm in which it may be used is 7 or 8 cm.

from the anterior elbow crease. There must be a movable scar at the end of the bones, in as much as the degree of up and down movement of the ivory pins determines the extent of opening and closing of the hand that will result. The pin is passed through a skin lined tunnel and it is connected by a chain to a bar from the lower end of which a metal rod goes to the hand mechanism. One side of the mechanism is the thumb and the other the index finger and the remainder of the hand. In instances in which the terminal scar is fixed reamputation must be performed. The bones are divided 3 cm. shorter than the muscles and the deep fascia but not the muscles is sutured over the end of the bones to give a free scar. From 5 to 10 days later active exercises and massage are instituted. Constant practice is a requisite.

The tunnels are made under local anesthesia so that the best muscle groups may be selected for the tunnel.

An area of about 3 finger breadths, or about 5 by 5 sq. cm. is mapped out about 5 cm. from the end of the stump. Three sides of this square are freed to form a flap with its base either on the medial or on the lateral side. The flap consists of skin and subcutaneous tissue including the deep fascia, folded into a tube with the skin surface on the inside.

A blunt pointed muscle dilator is passed through the muscle fibers along a tract about 1 cm. deep only a thin layer of muscle fibers being picked up

The tube of skin is then passed through this tunnel in the muscle and is fixed with three sutures to the skin edge of the side opposite the base of the tube. A Thiersch skin graft is cut and sutured in place over the remaining raw area.

The first dressing is done in 10 days. Then the pins, from 5 to 10 cm. in diameter are inserted. Exercises are maintained and in about 3 months an artificial limb is fitted.

The prosthesis. The artificial limbs are of light aluminum covered with leather. There are windows where the pins emerge to be attached to a metal loop at each end. In the forearm, contraction of the flexor group opens the hand, and contraction of the extensor group closes the hand. In the upper arm, contraction of the biceps closes the hand, and contraction of the triceps opens the hand. A strap from the ipsilateral shoulder pronates the hand and the spring supinates it again. A strap from the contralateral shoulder flexes the elbow and gravity extends the elbow. There are locking devices easily manipulated by buttons on the outside that lock the elbow in a fixed position and the forearm in a fixed position of rotation, if desired, and there is one at the wrist that locks the hand grip. A pencil may be grasped between the thumb and opposing hand and by locking the hand mechanism the grip is maintained without muscle effort. The hand can close further but cannot open.

C. FRED GORRINGER, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Hodges, H. H. and Freeman, N. E.: Thrombophlebitis on the Medical Service of a General Hospital. *Am J M Sc.*, 1947 213 226

The subject of thrombophlebitis and embolism has received increased attention in the surgical literature during recent years. The authors had occasion to study 20 instances of thrombophlebitis occurring in 9 patients all of whom were American soldiers. They discussed the diagnosis and divided the cases into (1) thrombophlebitis limited to the calf veins (2) thrombophlebitis limited to the calf and femoral veins, and (3) iliofemoral thrombophlebitis. They discuss their treatment and results and summarize as follows:

Ten instances of thrombophlebitis in the lower extremity were observed on the Medical Service of a General Hospital during a 4 month period.

Eight of these cases developed in patients with scrub typhus fever.

Early diagnosis was not achieved until they began to look carefully for the early signs.

In the authors opinion, treatment of thrombophlebitis should be individualized according to the location and extent of the lesion.

a. Thrombophlebitis confined to the calf veins was treated by lumbar paravertebral sympathetic block with uniformly good results. This procedure probably tends to prevent central propagation of the thrombus. Embolism did not occur and the patients were spared the prolonged disability which follows ligation of the femoral vein. The use of heparin or dicoumarin in these cases might help prevent propagation of the thrombosis. However its use is usually unnecessary. The concomitant use of anticoagulant and lumbar sympathetic block is prohibited by the danger of retroperitoneal hemorrhage.

b. Thrombophlebitis involving the calf and femoral veins was treated by proximal ligation. Sympathetic block was used only for relief of the pain after ligation. In a case of thrombosis of the calf vein with extension into the femoral vein, paravertebral procaine block prior to femoral ligation was followed promptly by pulmonary embolism.

c. Iliofemoral thrombophlebitis was treated with heparin, high ligation being inadvisable in these sick patients. The results were satisfactory.

This choice of therapeutic methods for the treatment of specific thrombotic lesions seems rational. It has been successful thus far in preventing embolism and in minimizing disability.

In addition to these specific measures all three groups of patients were treated by elevation of the extremity, administration of a compression bandage bed exercises, and early mobilization.

The authors observations suggest that all cases of iliofemoral thrombophlebitis do not necessarily re-

sult from extension of a thrombosis of the calf vein such a process may originate occasionally in the iliofemoral region.

PAUL MACKELL, M.D.

Blalock, A.: The Use of Shunt or By Pass Operations in the Treatment of Certain Circulatory Disorders, Including Portal Hypertension and Pulmonic Stenosis. *Ann. Surg.* 1947 125 129.

The purpose of this article was to discuss certain abnormalities of the circulatory system in which treatment by shunt or by-pass operations is proving effective or may be found to be useful. Particular emphasis has been placed on the treatment of portal hypertension and pulmonic stenosis.

Before the discussion of the individual disorders some general remarks pertaining to blood vessel anastomosis were made. It is most important that the anastomosis shall remain patent. This is dependent to a considerable extent upon the caliber of the vessels that are used and upon the expertness with which the anastomosis is performed. The anastomoses most apt to remain patent are those in which there is the greatest difference in pressure on the two sides of the union. It is probable that the anastomosis of a systemic artery to a vein would be most likely to remain patent, that of a systemic artery to a pulmonary artery would rank next, of an artery to another systemic artery would rank third and a vein-to-vein anastomosis would be least apt to remain open.

A vein-to-vein anastomosis is more apt to remain patent when the suture method is used as compared with the anastomosis method employing the vitallium tube. In the anastomosis of large arteries, such as the aorta, the author is of the opinion that the suture should be an everting one and should include the entire thickness of the wall of the aorta. In many cases only an end-to-end suture is feasible in others an end-to-end anastomosis may be done, as for example, the end of the splenic vein to the side of the renal vein. It was found that 90 per cent of the splenorenal anastomoses remained patent when the end-to-side method was used whereas only 73 per cent of the end-to-end anastomoses remained open.

The author notes that a by-pass or shunt operation should be considered in hypertension of the portal vein or its tributaries. Although it is not always possible to be sure as to the nature of the block it is usually possible to predict, on the basis of studies of liver function whether the hypertension is due to portal cirrhosis or to extrahepatic blockage. A discussion is presented relative to information to be gained about the nature of the block from certain clinical observations. Portacaval shunt (anastomosis of the portal vein and inferior vena cava) operations are still in the experimental stage and much remains to be learned about the choice of patients for operation and the choice of operative pro-

cedure. It does appear however that the principle of portacaval shunts in the treatment of ascites and gastrointestinal bleeding is a much sounder one than those of operations previously advocated.

The following impressions which have been gained from the author's experience are presented (1) anastomosis of the portal vein and inferior vena cava is preferable when indicated to a splenorenal union in that it will conduct more blood and is more apt to remain patent, (2) if a splenorenal anastomosis is performed suture of the proximal end of the splenic vein to the side of the renal vein is preferable to an end-to-end anastomosis (3) suture of the divided distal end of the portal vein to the side of the inferior vena cava is preferable to a side-to-side anastomosis since the opening is more apt to remain patent and (4) it is not necessary to occlude the inferior vena cava completely while performing a portacaval shunt.

A shunt or by-pass operation may be indicated in the treatment of coarctation of the aorta. Other conditions besides that of pulmonary stenosis in which a shunt or by-pass operation may be used are briefly mentioned. The splenic artery may be used for conducting blood to the left kidney the splenic artery may be used as a replacement for the first part of the superior mesenteric artery. The internal mammary vessels, when joined to the mesenteric vessels of a segment of jejunum, may be employed in the creation of an artificial esophagus. In aneurysm of the first part of the common carotid artery the adjacent subclavian artery may be substituted for the carotid.

In cases of pulmonary stenosis or atresia, the underlying principle in the choice of patients for operation is that there be inadequate flow of blood to the lungs. Although the clinical history may be of some aid the two outstanding features are that (1) the pulmonary artery is small in size and (2) there is roentgenographic evidence of absence of congestion in the lung fields. A diagnostic method which should be available and which has not been used to the desired extent is that of visualization of the heart and great vessels after the injection of radiopaque substances.

In most instances the author prefers an end-to-side anastomosis, that is, the union of the end of a systemic artery to the side of one of the two pulmonary arteries. In most patients who are more than 2 years of age the subclavian artery is the vessel of choice. Discussions of the technical features of the operation are presented. Two hundred and forty three patients who were thought to have the "tetralogy of Fallot" have been operated upon by the author and his associates. The over-all mortality rate has been 21 per cent. The mortality rate in the second 100 patients was 15 per cent. In the patients (approximately 147) in whom an anastomosis between the end of a subclavian artery and the side of the pulmonary artery was performed the mortality rate was 9 per cent. On the other hand the mortality rate among those in whom the carotid or innominate artery was used (approximately 57) was 33 per cent. It was also noted that because of a long waiting list

of patients, those chosen for an early operation were doing rather poorly but postponement of operation would have been a serious risk. There have been no instances of pyemia or mediastinitis in the patients operated upon.

HARRIS F. THURSTON, M.D.

De Takats, G., and Evey M. H.: Peripheral Vascular Sclerosis. *J. Am. M. Ass.* 1947 133 441

Peripheral vascular sclerosis is the overwhelming single cause of deficient arterial circulation in the lower extremities. Four grades of this disease can be recognized. The authors give the data of a series of 57 carefully selected cases and group them according to the severity of the disease.

Group 1. These patients have diminished or absent pulsations of the foot or lower leg. The skin is warm and the color of the feet is normal. They can walk a distance of from 2 to 6 blocks without pain. Lumbar sympathectomy was performed in 18 of such patients. The authors state that the improvement in walking in some of these has been dramatic. These persons have been restored to their full earning capacity. In 8 other patients included in this group there was no improvement in the claudication although the foot and lower leg became warm and dry. The authors raise the question as to whether claudication can be relieved at all by sympathectomy.

Group 2. The feet of the patients in this group are pulseless, and their ability to walk without pain is reduced to less than 2 blocks. Trophic changes may still be absent, although the feet are cold and dry and a single toe is often cyanotic. A cold and moist foot always gives a better prognosis because such patients exhibit a heightened sympathetic tone the release of which warms up their skin. Of 8 patients in this series only 1 required amputation. Sympathectomy helps in that cyanosis may disappear and a pre-gangrenous leg may be converted into a warm dry extremity.

Group 3. There is pain at rest and intractable ischemic neuritis. Walking may be less painful or even offer relief when rest in bed is difficult. When the foot is ice cold and when arteriolar obstruction and capillary paralysis are obvious from the pronounced dependent rubor sympathectomy is of no use and may precipitate gangrene. In one form in which the pulseless foot is hot, an osteoporotic and causalgic state exists, and after a satisfactory response to sympathetic block, a sympathectomy has averted amputation.

Group 4. The patients exhibit ulceration and gangrene of the digits or parts of the foot. The lesion is dry and not too painful. The popliteal pulse is absent, and possibly the femoral pulse is also absent. Supracondylar amputation at the level of positive histamine flares used to be the surgical procedure of choice in these patients. However, a sympathetic block may so shift the level of circulatory efficiency that a lower leg or a metatarsal amputation can be tolerated. This is an important group since patients can be discharged with a heel

Fig 1 (Servelle) Left, Aneurysm of the right popliteal artery Right, Same patient. Aneurysm of the left popliteal artery

stump below the knee or at metatarsal levels, but they would never have tolerated such an amputation without sympathectomy. The author describes the type of amputation used in such cases. He then discusses the technique of lumbar sympathectomy on the lower extremity. The results were as follows:

1. The extremity warms up faster and cools more slowly on direct exposure. Reflex effects of heat and cold are ineffective.
2. The high vasoconstrictor tones in the sitting or standing position is abolished.
3. Vascular exercises such as intermittent venous hyperemia are more effective.
4. Any cross stimulation between sympathetic and demyelinated sensory fibers is abolished.
5. During effort the sympathetomized extremity will not cool off on the contrary it may become warmer.

The authors summarize their article as follows:

A group of 57 patients with vascular sclerosis of the lower extremities has been studied. If after preliminary block of the lumbar sympathetics the temperature of the digits rose, walking ability improved and generalized vascular involvement was not extensive a lumbar sympathectomy was performed. In one group of patients this operation resulted in a dramatic increase in walking ability, in a second group amputation was averted in a third group intractable neuritic pain of the causalgic type was benefited and in a fourth group amputation could be performed at a lower level. In rigidly selected cases of peripheral arteriosclerosis, lumbar sympathectomy has been of great value. PAUL MERRILL, M.D.

Servelle, M: Arteriography and Heparin in the Surgery of Arterial Aneurysms. (Arteriographie et héparine dans la chirurgie des anévrismes artériels.) *Res chir., Par.*, 1946 65 373

A frequent error in the differential diagnosis of arterial aneurysm is that dilatation of the vessel in

its whole length (mega artery) is mistaken for an aneurysm. In this condition arteriography is an invaluable diagnostic help. Since the two disturbances require a very different kind of treatment, arteriography in all doubtful cases prior to surgery seems to be indicated. Furthermore in cases of true aneurysm arteriography gives an exact picture of the size and position of the sac and its relation to the artery and enables the surgeon to decide before the operation which type of intervention is indicated.

The second part of the article is devoted to the use of heparin as an anticoagulant in the surgery of aneurysm. The author prefers heparin to dicoumarol because its effect takes place more rapidly and the heparin is eliminated in a much shorter time than dicoumarol. Consequently there is no danger of secondary hemorrhage.

Heparin is applied topically as well as by intravenous injection. Preoperatively the suture material for the arteries is soaked in a 10 per cent heparin solution and during the operation the arterial wall and the aneurysmal sac are irrigated with a 2 per cent solution in saline solution. After the operation, 2 c.c. of heparin are injected intravenously for 3 days. As suture material for the arteries, the author uses linen (No. 0 or 1) and warns against the small threads of silk or catgut (000 or 0000) which are not resistant enough.

WERNER M. SOLMITZ, M.D.

BLOOD TRANSFUSION

Sabaneev D P: Plasmol S-25. *Vrachebnoe Delo* 1946, No 9, 618.

The Kiev Institute for Blood Transfusions and Emergency Surgery has produced a preparation from the blood plasma and serum of the human being which has been designated plasmol S-25. This material is for use in the method of tissue therapy developed by Filatov. The material has been dried in vacuum

at various temperatures (not above 30 C) and under various conditions of temperature and humidity so as to vary to any desired degree the development of the "conservation factor." The resultant product can then be dissolved in any desired amount of fluid and injected subcutaneously or intracutaneously under exact conditions of dosage. The present product was the twenty-fifth in the series and was thus designated plasmol S-25.

When the plasmol is injected into the ear vein of the rabbit it produces an initial vascular spasm (up to 30 seconds) followed by an intense hyperemia lasting from 15 to 30 hours. When perfused through an isolated organ (the kidney) in 1 to 1,000 dilution the rate of drop coming from the corresponding veins is reduced to one-half. When injected subcutaneously some sensation of burning is produced however in more than 3,000 injections in the human being there was not a single unpleasant incident (abscess, phlegmon).

The preparation when injected into and under the cicatrices and keloids resulting from burns, or even when injected at a distance from the lesion in 27 patients in a dosage of 1 gm. every 5 days, resulted in marked improvement in 14 patients and improvement in 9. In the remaining 4 patients bits of tissue were transplanted instead of the plasmol. Two hours after intracuticular injection the scar would undergo an intense hyperemia lasting for 2 or 3 days and the following day there would be some edema. At the end of 6 weeks the scar would be soft and flattened, and among the cases in which the cicatrix was subsequently excised, there was not a single instance of recurrence. In 3 patients with warts, the warts had disappeared after 3 weeks of treatment, and injections of the plasmol made directly under the warts hastened their disappearance which occurred after 10 or 25 days. When treatment was started several of the patients were suffering from a mild case of boils these lesions would immediately dissolve in a serosanguineous liquid and dry up in a period of 2 or 3 days.

Following the subcutaneous injection of 1 gm. of the plasmol in the groin of patients with acute orchitis, the temperature would fall by 1° in from 6 to 8 hours, the pain would disappear within from 30 to 40 minutes and the infiltration would leave without trace after from 7 to 10 days. The same results were obtained in men with acute epididymitis, after 2 or 3 weeks, and in women with salpingitis, oophoritis, and parametritis the results were just as dramatic.

Of a group of 139 patients with ulcer who were receiving stationary or ambulatory treatment, some had undergone gastroenterostomy and some had duodenal ulcer and stomach ulcer. Treatment in these cases consisted of 4 injections of 1 gm. of the plasmol at intervals of from 5 to 7 days. The injections were administered under the skin of the abdomen along the outer third of a line drawn from the navel to the twelfth rib on the right side. In the patients so treated improvement would be noted by the end of the third week the pain had disappeared, and also the acid belching and vomiting. Analysis of the gastric content demonstrated marked lowering of the total acids. In a few patients the niche was observed to disappear after 6 weeks of treatment. Results were so good that now the patient is put on a general diet on the second day following the second injection. The patients soon regain their weight, become active, and their appetite improves. The roentgenological findings of the stomach content and stool show marked improvement and active regeneration appears in the blood picture.

A special group of cases was made up of patients with nerve diseases: hemiplegia on a traumatic basis (3 cases), lumboschialgia (9 cases), spondylorheumatism (4 cases) and neuralgia of the trigeminal nerve (3 cases). In the lumboschialgias the stiffness in the loins and pains disappeared in 20 or 30 minutes after the first injection and no repetition of the injection was necessary. Voluntary movements of the extremities in the cases of hemiplegia and the power of speech in 1 patient with an accompanying aphasia, were recovered after 6 weeks of treatment. The trigeminal neuralgias disappeared after the fourth injection.

A large group of cases presented nonhealing wounds and trophic ulcers. In these the plasmol was injected in 1 gm. doses immediately under the sore at 5 day intervals. On the second day after the first injection the ulcer began to clear up, the granulations assumed a healthier appearance and in some instances an intense phagocytosis appeared, which increased with the following injections. The same results were attained with injections at a distance. The wounds or ulcers were completely healed in 2 or 3 weeks, no matter how long the ulcer had been present before treatment.

Future articles will give greater detail regarding the chemical and mechanical mechanisms, as well as the experimental work on this preparation, which is being carried on at the present time.

JOHN W. BRIDGEMAN, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Wangensteen, O. H.: Care of the Patient before and after Operation. *England J. M.*, 1947, 236, 121

Poor risk patients undergoing extensive surgery demand careful consideration as to water requirements. The urine output and the specific gravity of the urine serve as fairly satisfactory guides in determining how much fluid to give. A 24 hour output of 1,000 to 1,500 c.c. of urine is optimal. A fluid intake of 2,500 to 3,000 c.c. or 1,000 to 1,500 c.c. of fluid is optimal. Glucose solutions in water are given on the day of operation. If an inlying duodenal tube is in place to which suction is being applied allowance must be made for such electrolyte loss. A good working rule is to estimate the loss of sodium chloride at 5 gm. per liter of gastric aspirations. In the author's experience the weighing scale is superior to other procedures in determining early variations in the state of hydration. Patients are weighed daily before surgery to establish the normal weight.

Postoperatively beginning usually on the day after operation the patient is weighed either on a portable scale brought to the bedside or by means of a bedside scale which permits weighing the patient in bed. The method can be readily carried out to an accuracy of 100 gm. In a patient weighing 70 kgm this figure represents a 14 per cent of the body weight. Over the short postoperative period when the weighing scale is utilized, it is reasonable to assume that most of the weight fluctuation represents differences in body hydration. The basic caloric requirements of the patient after operation are usually met by the daily intravenous administration of 3,000 to 3,500 c.c. of 10 per cent glucose solution. If an inadequate amount of sodium chloride is given at the same time a liberal urine output may follow and dehydration will ensue in a few days if the electrolyte loss is not restored. Saline solution is ordinarily satisfactory to restore the electrolyte balance. It is the practice of the author to await evidence of diuresis before utilizing intravenous saline solutions.

Patients whose food intake has been poor and who have lost considerable weight are poor subjects for operation. These patients are considerably improved by feeding a mixture rich in proteins and carbohydrate and low in fat provided there is no pyloric obstruction. For those patients with pyloric obstruction the preoperative preparation is accomplished by the intravenous feedings of amino acids, plasma and glucose. The diet should be fortified with adequate amounts of vitamin C and vitamin K.

FRANK F. KANTAK, M.D.

Marino, H.: Surgical Treatment of Gigantic Nevus (Tratamiento quirúrgico de los nevus gigantes). *Prensa med. argent.*, 1946, 33, 1321

Nevi of many varieties (verruccous pilous moluscum hypertrophic, pigmentary avascular vascular) are common dermatologic diseases. In addition to a nonesthetic aspect they always present the possibility of malignant change which indicates radical treatment even if a small depressed scar is left. The author does not favor prophylactic extirpation of all nevi but sticks to the rule proposed by Adair: Leave the brown moles alone, be concerned only with those which contain definitely black pigment.

Once extirpation is decided upon it must be radical in order that no after effects will occur. It can be performed by galvanocautery, diathermocoagulation or surgical excision. As for pigmentary moles with melanotic cells, the only possible treatment is surgical excision with minimum disturbance of the dangerous cells. Most delicate handling of the tissues and incision at a good distance from the tumoral border.

The problem becomes more serious if the nevus is very large. Gigantic nevi always of congenital origin may cover any part of the body. They are often tuberosus hypertrophic, pigmentary or papillomatous. The only possible treatment is surgical excision and the raw surface is covered with a graft, either free or pedicled. In cases of this type, if the operation is to be in one stage it is advisable to prepare the

Fig. 1 (Marino) Black nevus of hand and forearm treated with coagulation, solid carbon dioxide and irradiation. Bad scarring with radiodermatitis, loss of extensor tendons and ankylosis of the joints with deviation of the hand. Large pedicled graft from abdomen. The patient is satisfied and does not want the complete plastic repair.

patient carefully to avoid the danger of shock due to the large bleeding area left by the extirpated tumor and the donor graft. Blood and plasma transfusions will be of value during and after the operation. Naturally if the patient's condition requires it, the procedure can be divided in more stages. However, the author prefers the extirpation *in toto* (one block of the diseased tissues) followed by immediate grafting whenever possible, even if there was some infection of the lesion.

As for the skin required to cover the raw surface, preference is given to the free graft, the pedicled graft being employed only to cover joints and tendons, or in case of lack of subcutaneous tissue. A free graft will almost always give good results as the tissues under a nevus can be considered as normal. On the face the full thickness graft can be used, but a good thick split graft is equally satisfactory and does not present the problem of coverage for the donor area.

Technically all cases must be carefully studied as there will be difficult problems of selection of the donor surfaces, immobilization, and dressing, which are the key to success. Padgett's dermatome is a great help in obtaining the necessary skin and long strips may be cut which in some cases are wrapped around a limb as a cutaneous bandage and fastened with only a few running stitches. Electrocoagulation is used to control bleeding. As for the dressing, it is fixed by an immobilizing plaster cast.

HENRIER MARINO, M.D.

Macomber, W. B., and Rubin, L. R.: Tubed Pedicle Complications in Repair of Massive Tissue Defects. *Plast. Reconstr. Surg.* 9:47 10.

In a study of more than 300 tubes which was made at an Army General hospital, the authors have listed the complication which developed in the making and transferring of tubes. In these cases, despite various minor erosions, all but 3 transfers were completed.

The tubed pedicle, with its network of blood vessels in the subcutaneous layer provides an excellent medium for filling large defects. The principles of

massive tissue movement are the same in all flap transfers. Several factors must be remembered. The main blood supply to the skin and subcutaneous tissue comes from vessels deep in the fat. These usually course just above the deep fascia with branches going upward to form an anastomosis beneath the dermis. Another layer of networks can be found just under the malpighian layer. It becomes apparent from this principle that in all massive tissue movements the fat and the deep fascia must be included in the flap if the blood vessels are to be included for nutrition. Tension serves to stretch the elastic fibrils in the skin and constrict the vessels, which causes death of the tissue. The graft is dependent upon a delicate blood supply therefore gentle handling of the tissue is essential. Rough manipulation causes thrombosis of the blood vessels. The skin itself is never held with a forceps. Blunt dissection with scissors or the fingers is never used to separate layers. Hooks are excellent to hold tissue. Raw surface must not be left uncovered unnecessarily without moisture. Tissue holding by the hands should be limited to absolute necessity.

Perhaps all the necrosis along the line of suture can be traced to tension. Too much fat is included in the tube or conversely the tube is insufficient in width. The safest way to avoid this complication is to mark out the prospective tube flap on the skin with methylene blue. Only one incision is made at first. The flap is undermined completely from this one incision, dissection being done with a sharp knife along the fascial plane. All bleeding is carefully stopped. When the undermining reaches the line previously marked on the skin, an attempt is made to fold the skin under as it is to tube it. The authors indicate that turning a tube with No. 8 silk for the skin only is adequate.

The need for subcutaneous sutures or heavier skin silks is indicative of too much tension. Should the tube be too tight despite all of the precautions taken, it is advisable to employ a split skin graft on the under surface of the flap, as well as on the donor site instead of trying to make the tube. Whenever a very long tube is used, the length must be balanced by adequate width to insure an adequate blood supply at the center of the tube.

The authors warn against completion of delayed transfer in one stage because necrosis of the tip may result. Infection and hemorrhage are the main complications of secondary delays. In this delay all long vessels coming into the distal end of the flap are ligated.

The procedure of transfer of the tube and flap requires great care. The flap is lifted from the donor site and both the tube and flap are carefully observed. Any blanching is a signal for return. The complications are many. Arterial changes may be noted at once by blanching.

Poor venous return can be noted early by bluish discoloration. To facilitate venous return, it is best to have the recipient site at a higher level than the donor site. The flap must fill the defect. It cannot, however be stretched in any way. Normal skin ten-

Fig. 1. (Macomber) Illustration of folding of skin flap to see if it will tube easily. This must be done the entire length of the tube, since folding at the corners diminishes the length of the free tube. The easy folding must be present along the entire desired free length.

SURGICAL TECHNIQUE

sion is necessary to prevent kinking of the vessels. Any twist, kink or angulation of the tube will interfere with the circulation and cause necrosis.

C. FERN GONZALEZ, M.D.
Escobar Pacheco, A.: Venous Ligation in Pulmonary Infarction (Ligadura venosa en los infartos pulmonares). *Arch. Soc. C. Hosp. Santiago*, 1946, 16: 555

In a study of 15 cases of pulmonary embolism of which 7 revealed mitral involvement, 3 aortic insufficiency, 2 phlebothrombosis, 2 Hodgkin's disease, and 1 hypertension the author found the following symptoms: hemoptysis in 12, cyanosis a disease, pain in 6, subicterus in 12, cyanosis in 7, costal rigidity in 5, doubtful Homans sign in 3, costal rigidity in 1 and pain in the calf in 1.

Venous ligation was practiced in all of the cases. In 1 case was subjected to ligation and section of the femoral vein, 5 to ligation and section of both femoral veins, 6 to ligation of both iliacs and 3 to ligation of the inferior vena cava. All of the operations were done in three stages. First a simple ligation of the internal saphenous was done. Then simultaneous ligation of the collateral after aspiration by means of a cannula, both the afferent and efferent vessels expelling clots. In the second stage, a 5 cm. vertical incision medial to the palpable femoral artery was made and on reaching the femoral vein the afferent portion was ligated twice while the efferent was between the ligatures. The third stage was done by no impairment of the circulation of the limb as evidenced by edema and cyanosis. In this stage the external iliac were ligated by means of a 5 cm. incision above Poupart's ligament, the location of the femoral artery being at the midpoint of the incision. The skin was opened and the aponeurosis of the external oblique muscle was incised. With the separation of the internal oblique and transversus abdominis muscles, the transversus fascia is next opened which brings into view the iliac artery and vein. A Deschamps needle is used to pass a ligature from the lateral to the medial side to avoid the risk of puncturing the artery. The vein is ligated without section. In the last stage the vena cava is ligated through the pararectal incision on the right side, which passes through the external oblique muscle and the retroperitoneal tissues. The vena cava is ligated above and transverse abdominal muscles, peritoneum, and the union of the common iliac and below the renal veins. Local anesthesia was used in all except 1 case.

The circulation was re-established by means of the pudendal, circumflex epigastric, and gluteal veins which unite with the internal iliac and gluteal veins, or parietal, ilio-lumbar and lateral sacral veins which empty into the inferior vena cava by means of the azygos.

This procedure brings about a marked and immediate improvement in the subjective and objective condition of the patient in relation to the cardiac

insufficiency. It was shown that there is absolutely no harm done to the return flow of the legs by ligating both femoral veins or both iliacs, and even the vena cava, at the point indicated. Not only is it necessary to intervene early before the thrombus reaches a place not accessible for venous ligation but also to ligate as high as possible.

ARTHUR F. CYRILLA, M.D.
133 and 1947

Stewart, J. D.: Wound Shock. *J. Am. M. Ass.* 1947

Although it is recognized that there are many causes of shock in battle casualties there is considerable evidence to indicate that loss of blood dominates the early picture in the majority of severe wounds inflicted by penetrating high explosive missiles.

A group of gravely wounded nontransportable casualties were examined in forward field hospitals a few miles behind the battle line. All were in actual or imminent shock on admission. All were in actual traumatic shock on admission. Compound fractures, traumatic amputations and penetrating abdominal and thoracic wounds predominated in the 200 cases studied. In the majority of cases the wounds were multiple. Seventeen of the 200 patients died under observation. The average interval between wounding and admission was 4.9 hours (maximum 25.2 hours). Plasma volume plasma reading were determined immediately after admission, and again 24 hours later after restorative therapy and operation. Further determinations were made subsequently. Reduction in blood volume of the patients was found to be the rule just after admission. Despite the fact that the average patient had received a pint of plasma and a small amount of blood, his blood volume had risen to 95 per cent. In some cases oligemia was still present at the end of 24 hours, despite replacement therapy and presumably further loss of blood had taken place. Undercorrection was most common. It was found that at the end of 25 hours the average was still 5 per cent below normal, and there was an associated reduction in the hematocrit reading and on the basis of this study the average soldier receiving a serious shock producing wound must be given at least 2,000 c.c. of blood if the volume of blood is to be restored to approximately normal in 24 hours. Studies made later show that the quantity of blood required to maintain normal hemoglobin and plasma protein values during the early period of repair of the wound and convalescence.

It appears that in traumatic shock some correlation exists between the lowering of systolic blood pressure and the degree of oligemia that is the initial blood volume is lower in those cases with lower systolic blood pressure readings. Thus in 5 patients who were admitted with a systolic pressure of zero the average initial blood volume was 58.7 per cent in 20 patients with an initial systolic blood pressure of less than 100 the initial average blood volume was

77.3 per cent and in a group of 21 patients whose systolic blood pressure at the time of admission was 100 or over the initial average blood volume was 81.6 per cent. If the entire group of severely wounded casualties is divided according to the initial reading of the blood pressure, it is found that the amounts of plasma and blood administered in the first 24 hours showed some correlation with the blood pressure readings. The lower the blood pressure, the greater the amount of blood and plasma considered clinically necessary and given in restorative therapy.

It is believed that the average loss of blood was 2,500 to 3,000 c.c., or about half the normal volume of blood. The depletion of blood volume in traumatic shock could conceivably be due to loss of water and electrolytes, loss of plasma or loss of whole blood. Accordingly the concentrations of plasma protein, red cells, and nonprotein nitrogen in the plasma were of interest. It was found that the average concentration of protein in the plasma on admission was 6.5 gm. per 100 c.c., and that the average red cell hematocrit reading was 37.3 per cent. The average nonprotein nitrogen value in the plasma was 30.8 mgm. per 100 c.c. These values offer confirmatory evidence of the absence of anhydremia. Hemodilution, which is a characteristic physiological response to severe hemorrhage, was a uniform finding in this group of patients.

If one considers the typical hematic changes in wound shock, namely oligemia and reduction in concentration of hemoglobin and plasma protein, there seems to be little room for debate over the relative merits of plasma and blood in repair. Evidence indicates that massive quantities of blood are lost. Relief of tissue anoxia, under the circumstances, is an urgent requirement to be met by replacement of circulating hemoglobin values and improvement in the amount of oxygen carried by the blood.

During convalescence it was evident that blood volume plasma protein concentration, and the hematocrit reading remained low for days or weeks. Plasma volume soon became normal. The persistent deficit of hemoglobin and plasma protein is accompanied by overdilution, and some sacrifice of concentration is made in restoring the volume of blood to normal. The operation is at times essential to resuscitation and it is an important matter of judgment to know when to operate. The average interval between admission and operation was 4 hours.

Of the 100 gravely wounded patients, 17 died under observation. Only 5 died in relation to a possible state of "irreversible shock." However persistent hemorrhage and insufficient replacement of blood could not be excluded as likely causes of death in these 5 patients therefore this concept is open to question.

The present article is largely concerned with wound shock which is due to severe trauma, not including burns, and for the most part is still uncomplicated by such lesions as clostridial myositis, spreading peritonitis, or pulmonary thromboembolism.

LEROY J. KUMBARSKA, M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Young, H. H., and Ghormley R. K.: Accidents on the Farm. *J Am M Ass* 1946, 32 768.

In the 9 years from 1935 through 1943 575 accidents on the farm caused the person injured to come to the Mayo Clinic. The majority of these patients came from the surrounding four or five counties, but the total number is not an index of the total farm accidents that occurred in those four or five counties. The clinic total may be said to represent with fair accuracy the number of serious accidents that occurred in these counties during that period. Included in the study were all accident cases encountered at the clinic which were due to falls, farm machinery livestock, injuries in the farm home buzz saws, etc. Omitted were all automobile and highway accident cases.

Falls led all other causes of accidents in this series and carried a mortality rate of 3 per cent per 100 accidents. The commonest accident of this type was that in which the patient fell off some piece of farm equipment. Accidents attributed to farm machinery followed falls in a close second place as the cause of farm accidents in this series there were 186 such accidents. Although there were no hospital deaths in this group, the morbidity rate was extremely high. Exactly a third of the patients in this group suffered from traumatic amputation of a part or the whole of one or more extremities. The tractor caused the largest single group of accidents and was followed closely by the corn picker, corn shredder and buzz saw. The third most frequent cause of the accidents in this series was livestock there were 104 such accidents. The mortality rate in this group was 5 per cent, 3 deaths were due directly or indirectly to horses, and 2 deaths were caused by bulls. Seventy seven of the accidents were caused by the axe, by falling trees, or by a group of unclassifiable causes. In the entire group of 575 accidents in this series, the injuries sustained consisted of 396 fractures, 65 traumatic amputations, 25 instances of transverse myelitis, 9 of perforating perineal wounds, 7 avulsions of the skin of the penis and scrotum, and 205 miscellaneous injuries. In this series of cases there were 18 deaths, a mortality rate of 3 per cent per 100 cases.

An educational program for the farmer is the first step in decreasing the number of accidents on the farm.

Brown, A.: Morphological Changes to the Red Cells in Relation to Severe Burns. *J Path. Bact., Lond* 1945 53 367.

In a previous study of the hematological changes in burns it was shown that burns involving more than 15 per cent of the body surface are frequently followed by a rapidly occurring moderately severe anemia which is associated with a slight increase in the mean corpuscular volume, increased erythrocyte fragility and increased plasma bilirubin and

urobilin excretion. The present studies are concerned with the variations in mean corpuscular volume, mean corpuscular diameter and mean corpuscular average thickness in relation to variations in osmotic fragility and the mechanism of production of the anemia in severe burns. Hemoglobin was estimated photoelectrically. Saline fragility was determined quantitatively by comparison with a standard equivalent to 50 per cent lysis as determined by a Duboscq colorimeter. Red cell diameters were measured by microprojection on millimeter-ruled graph paper magnified to 1,000 diameters. Evenly spread cover slip preparations stained by Leishman's stain were used and 400 cells in each film were measured.

Investigation of the morphologic changes occurring in the red cells of 3 very severely burned patients showed that fragmentation of the red cells and microspherocytosis occur within a few hours of the injury and are associated with an increase in the mean corpuscular average thickness. The morphologic changes occurring in the red cells in burns can be attributed to the direct action of heat on the cells. The maximum effect is immediate fragmentation and destruction. If the damage is less severe, microspherocytosis is produced and the affected cells are unduly susceptible to the physiological trauma of the circulation. Hemoglobinemia and hemoglobinuria may occur according to the magnitude and rate of hemolysis.

FRANK F. KANTHAAR, M.D.

Gubern Sallaesche, L.: The Vegetative Nervous System and the Anesthetic Infiltration of the Sympathetics in Traumatology (El sistema nervioso vegetativo y las infiltraciones anestésicas del simpático en traumatología) *Cirujía apar. locomotor* 1946, 3, 97

All trauma necessarily produces a necrosis which brings into consideration adaptation mechanisms, the aim of which is to re-establish the physicochemical equilibrium of the tissues which are altered by the lesion. Humoral and nervous factors are in close correlation. The humoral factors are seen as a zone of static hyperemia surrounding the focus while this in turn is surrounded by a more extensive zone of active hyperemia produced by the liberation of histamine-like substances. Among the nervous factors is an axonic reflex, which in the periphery gives rise to muscular contracture and muscular atrophy and results in pain in the central portion. The healing of the necrosis is favored by rest and the active vasodilatation produced by local anesthesia and anesthesia of the sympathetics.

Treatment of 300 or more cases by anesthetic infiltration of the sympathetics resulted in a decrease of the pain and healing time. The following routine was carried out: the use of 3 infiltrations of novocain per week until the condition was cured or if a solution of novocain in oil was used only 2 infiltrations per week were necessary. After 15 or 20 days treatment with infiltration was suspended in the bone lesions and after 8 days in the traumatized tendons or aponeuroses. In trauma which manifests a doubt

ful mechanical disorder the first 2 infiltrations gives one an idea as to whether or not to apply orthopedic treatment, while sometimes the infiltrations only decrease the edema of the traumatized area, which makes complete mobilization possible. It also gives excellent results in post traumatic ulcers although sometimes ganglionectomy must be done. The draw backs to this procedure are as follows: (1) the technical difficulty especially in lumbar infiltration (2) the pain produced by the injection and (3) the limited time of action.

The best results were obtained when Feng's mixture was used which consists of novocain, acetylcholine and vitamin B. ARTHUR F. CIPOLLA, M.D.

Rustigian R., and Cipriani, A.: The Bacteriology of Open Wounds. *J. Am. M. Ass.*, 1947, 133, 224.

As part of a study of penicillin therapy in the management of wounds in Italy a total of 214 types of bacteria were isolated from 27 infected and 9 clinically clean wounds. 45.3 per cent (97) of the 214 isolates representing several genera, were obligatory anaerobes and 15.9 per cent or 34 cultures (streptococci and micrococci) were microaerophiles. This emphasizes the decidedly anaerobic environment of the bacteria in these traumatic injuries. The clean wounds differed from the infected wounds in the absence of pyogenic cocci. Beta hemolytic streptococci, *Staphylococcus aureus*, *Staphylococcus albus*, enteric streptococci, clostridium *Proteus*, *Pseudomonas* and coliform bacteria appear to be the species most frequently encountered. Other species less frequently reported include undifferentiated streptococci, an aerobic streptococci, micrococci, bacteroids, diphtheroids and bacilli.

The 214 bacteria isolated were differentiated under 3 functional entities: (1) toxigenic and/or invasive, (2) proteolytic, and (3) wound commensals. Of the toxigenic and/or invasive bacteria there were 33 in the following order: *Staphylococcus aureus*, hemolytic streptococci, *Clostridium perfringens*, *Clostridium novyi*, *Clostridium septicum* and unidentified clostridia.

It was noteworthy that bacteria-producing proteolytic enzymes occurred with a relatively high frequency in 103 of the 214 isolates tested. There were 63 in the hydrolyzing proteins group and 16 in the group producing hydrogen sulfide and/or visible gas from peptones.

There were 102 in the group of commensal bacteria. It is, of course, known that a synergistic relationship resulting in considerable wound involvement, may occur.

The combination of various bacteria in each of 36 wounds had been reported previously. In the final analysis, the interplay of metabolic activities of the true pathogens—the proteolytic bacteria, and those regarded as wound commensals, may be of major importance in the development of infection. The combined proteolytic reactions of several bacteria might be much more effective in causing septic decomposition of dead tissue than their individual reactions.

It is concluded that lines of demarcation of infection of wounds appear to be more practical clinically than bacteriologically. It is pointed out that although penicillin is very effective in the treatment of certain combinations of wound infection, surgical treatment is essential in the ultimate care of these infections.

LEROY J. KILGUSSEN, M.D.

Glenn, F.: Tetanus—A Preventable Disease. *Ann. Surg.* 94b, 124 30.

In the battle for Manila, the civilian population was not only subjected to injury from the besieging Americans, but also it suffered the restrictions of medicines, water, and food imposed by the Japanese. As a result, the incidence of tetanus among wounded civilians was high. In the San Lazaro hospital alone, 196 cases of tetanus developed in a group of 2 100 wounded non-combatants. However, not one case of tetanus developed in American military personnel engaged in combat in the same theater of operations. Compound comminuted fractures of the long bones, together with extensive soft tissue infection and damage, were most frequently associated with tetanus which appeared in from 3 to 30 days after wounding. Both varieties of tetanus, the local and general, were commonly found in the same patient. Common findings were trismus and orthostosis, followed rapidly by opisthotonus and the characteristic risus sardonius. Finally the tetanus progressed so as to involve the muscles of the abdomen, the neck, and the thoracic respiratory muscles. Trismus was present in all cases, whereas dysphagia occurred in about 75 per cent of all cases. Cephalic tetanus was not observed, but the deep reflexes were increased early in the disease. Protrusion of the eyelids or facial paralysis was observed in a small percentage of cases. Spasm of both the vesical and rectal sphincters was present in varying degree.

Surgical treatment in patients with tetanus, although of value for the sepsis and general condition of the patient, did not alter the course of the tetanus. Penicillin administered intramuscularly had no effect upon tetanus, neither did it show any effect when used topically in cases of local tetanus. The mortality rate from tetanus was 90 per cent with most of the patients dying within 10 days of the onset of symptoms. Morphine sulfate given in 0.08 gram doses proved of great value for the relief of the spasm. Paraldehyde and chloral hydrate were beneficial to a limited degree. The barbiturates were of little or no value. Ether in oil was effective in reducing convulsive seizures. Philippine physicians favored the use of a 25 per cent solution of magnesium sulfate given intramuscularly in 2 c.c. doses, but this caused severe respiratory depression. In the prewar years there were about 100 cases of tetanus yearly with a mortality rate of 25 to 35 per cent. There was little tetanus antitoxin available for civilian use.

There were no cases of tetanus among wounded soldiers in the Southwestern Pacific Area, while in the entire U.S. Army only 11 cases were reported during the war years and, of these, only 1 case developed in a combatant. This remarkable result was accounted for

only on the basis of immunization by tetanus toxoid and subsequent reinforcement by yearly booster doses.

Dr. Churchill, in discussing this paper reported that tetanus was found among the wounded German prisoners of war many of whom died. The Germans only immunized the Luftwaffe and special personnel. The Italian soldier was immunized against tetanus.

BENJAMIN G. P. SEAFROFF, M.D.

Lyons, C.: Chemotherapy in the Management of Wounds. *J. Am. Med. Ass.* 947 33 5.

The limited role of chemotherapy in the management of wounds is emphasized. The prevention of infected wounds is accomplished by active immunization with tetanus toxoid and initial surgical management. The major usefulness of chemotherapy is for the treatment of initial, reparative and reconstructive phases of the surgical management of a wound. This is most expeditiously accomplished by the systemic administration of the selected drug. Invasive infection demands the presence of hemolytic streptococci, staphylococci, or toxigenic clostridia. The clinical pattern or invasive infection indicates the presence of true pathogens but suppuration of a wound may be due to true pathogens, wound pathogens, or a combination. The combined experience of the last two World Wars has shown that the cleanly excised wound of soft parts develops invasive infection due solely to hemolytic streptococci. Suppuration of a wound is believed to be due more to the presence of a nidus of wound protein than to any specific bacterial virulence. No available antibacterial agent can completely sterilize an open wound. Topical, or local, chemotherapy has been discarded as ineffective and deleterious. Suppuration of a wound is an indication for repeated surgical treatment of the wound.

Closure, not sterilization, of the wound is the practical objective of the early phases of management. Efforts to abolish infection are necessarily integrated with efforts to expedite the healing of the wound. The most important accessory procedures in this regard are the correction of anemia and the restoration of tissue protein deficits. The known depressant effects of sulfonamide compounds on hematopoiesis, the intestinal synthesis of essential metabolites, and the appetite in general are further reasons to establish penicillin as the chemotherapeutic agent of choice in the management of wounds.

The author reviews the experiences which show that the persistence of devitalized tissue or sequestra prevents chemotherapeutic sterilization of the wound. Many of the organisms are naturally resistant, and the most important of these is the *Clostridium sporogenes* which is resistant to sulfonamide compounds, penicillin, and streptomycin. The important aerobic gram-negative wound pathogens are resistant to sulfonamide compounds in exudates from the wound, are insensitive to penicillin, and inherit or readily acquire a resistance to streptomycin. Clinical experience with established infection has shown that the sulfonamide compounds are extremely effective

against hemolytic streptococci have a limited usefulness against staphylococci, and are relatively ineffective against gas gangrene. Streptomycin is ineffective against the clostridia. With the exception of individually resistant strains penicillin is effective against all the potentially invasive pathogens. Sulfonamide therapy has been shown to be adequate for the wound endangered only by hemolytic streptococci. Penicillin is the drug of choice for all other wounds subject to invasive infection. No virtue is attached to combinations of these two agents in the treatment of infected wounds.

LEROY J. KLEINMAN, M.D.

Hirsch H. L., Dowling H. F., Virino J. J., and Rotman Kavka G.: Penicillin in Beeswax and Peanut Oil: A New Preparation Which is Fluid at Room Temperature; Absorption and Therapeutic Use. *J. Lab. Clin. M.* 1947 32: 34.

The authors report the results of their experience with the use of a modified preparation of penicillin in beeswax and peanut oil which is liquid at room temperature. Following the intramuscular injection of 300,000 units, 18 out of 20 subjects had detectable concentrations of the antibiotic 12 hours after injection while only 5 of the 20 had significant concentrations after 20 hours. Six hundred thousand units were injected intramuscularly into 36 subjects, 20 of the 36 had assayable concentrations after 20 hours while all except 2 had significant concentrations after 12 hours. The subcutaneous administration of 600,000 units of the preparation was carried out on 20 patients all but one patient had detectable amounts of penicillin in the blood stream at 24 hours.

This preparation was used clinically with satisfactory results. Seven cases of previous penicillin resistant gonorrhea responded to a single injection of 600,000 units of penicillin in wax and peanut oil. A case of subacute bacterial endocarditis due to *Streptococcus viridans* was treated with 300,000 units every 12 hours and was later placed on 600,000 units injected once a day. The patient made an uneventful recovery.

F. J. LEXMAN, M.D.

Morgenson W. J.: Toxic Reactions with Penicillin. *J. Am. M. Ass.*, 1946 132: 975.

The toxic reactions to penicillin are classified and discussed according to the mode of action of the antibiotic.

Penicillin may act as a direct toxin and primary irritant. Certainly this direct toxic effect is minimal in therapeutic concentrations. Purification apparently tends to reduce the toxicity. For practical purposes penicillin has a direct toxic action only when used intrathecally and this toxic effect is due to the penicillin itself rather than to the impurities. However, this does not condemn the intrathecal use of penicillin in proper dosage. Probably the dose should never be in excess of 30,000 units when given by this route.

Penicillin may act as an antigen. The immediate allergic reactions to penicillin usually occur in a

person with a previous exposure to penicillin, but a small percentage of people are primarily sensitive to the drug. This may be because the individual possesses a general sensitivity to moulds. It has been suggested that an exacerbation of a previous fungus infection or vesicular eruption involving the feet, hands and groins following penicillin therapy may be due to this sensitivity. Penicillin sensitivity may be of short duration or it may last for long periods, and the sensitivity may be epidermal or dermal, although the principal shock tissue appears to be the vascular system. The allergic symptoms produced by penicillin sensitivity are usually mild, but may be serious appearing as a severe angioneurotic edema with edema of the pharynx, larynx and lungs, which may lead to a fatal termination. When a patient is sensitive to crystalline penicillin as shown by a cutaneous reaction, or suspected when different lots from various manufacturers give symptoms continued therapy should be used with extreme caution.

Penicillin may cause therapeutic shock or Jarisch Herxheimer reaction if used in cases of syphilis. Focal reactions of intensified chancre or the appearance of cutaneous lesions may result, or systemic reactions of malaise, generalized aching, painful adenopathy and temperature elevation may occur. Such a reaction occurring during the routine treatment of gonorrhea in which syphilis is not suspected is at least very suggestive of concurrent syphilitic infection. Fever following the use of purified penicillin is rare and should always arouse a suspicion of the Herxheimer reaction.

Penicillin may have an indirect action on the pathological process. Particularly in late syphilis too rapid healing of cardiac and liver lesions may result in deforming sclerosis.

In the discussion of the article it is pointed out that the rate of sensitivity to penicillin is significantly increasing and it is therefore most important that this antibiotic not be administered for trivial or unnecessary conditions. F. J. LEXMAN, M.D.

Frisk, A. R., Hagerman G., Helander S., and Sjögren B.: Sulpha-Combination—A New Chemotherapeutic Principle. *Brit. M. J.*, 1947 1: 7.

The formation of renal concretions is one of the most serious drawbacks to sulfonamide therapy. The authors advocate using a mixture of sulfonamides to obviate this danger. The use of such a mixture is predicated by the following statements: the antibacterial effect of a mixture of several different sulfonamides is the sum of the effects of the various compounds; (2) the sulfonamides of a mixture as well as their acetyl derivatives do not affect the solubility of each other and thus the use of a mixture of sulfonamides considerably reduces the incidence of renal concretions; and (3) the compounds in a mixture of sulfonamides are absorbed and excreted independently of each other. Experimental evidence is presented in support of these statements.

A mixture of sulfathiazole, sulfadiazine, and sulfamerazine was considered most suitable. The mixture (sulfadial) was made in the following proportion: sulfathiazole 37 per cent, sulfadiazine 37 per cent, and sulfamerazine 26 per cent. The authors believe that if such a mixture is used, and if, in addition, a high diuresis with alkalinization is produced, the risk of concretum formation in a normal kidney will be almost eliminated. This mixture has given good results clinically. F. J. LEEMAN, M.D.

Fowler, E. P. Jr., and Sellman, E.: Otic Complications of Streptomycin Therapy. *J. Am. M. Ass.* 947 133 87.

The authors call attention to the possibility of the occurrence of neurotoxic symptoms involving the vestibular and auditory systems following streptomycin therapy. They review the observations of other authors and report their own observations in the cases of 81 patients. They state that a high incidence of vestibular disturbance and a sizeable number of cases of deafness, either transitory or permanent, will occur with the use of streptomycin in large doses of the drug are given over prolonged periods.

The onset of otic symptoms usually occurs from the seventeenth to the twentieth day if 3 gm. of the drug per day are given. The patients in the majority of cases recover from the deafness, and even if the caloric response remains negative the accessory balance mechanism compensates well for the totally dead labyrinth so that this need not be feared. The mechanism of these otic complications of streptomycin therapy is unclear as yet.

Because of the possibility of otic complications, it is believed that the use of streptomycin should be carefully considered but that when indicated it should not be withheld because of this danger. The occurrence of otic symptoms during streptomycin therapy should call for a reconsideration of the case before continuance of therapy. The authors suggest that one audiogram and vestibular test be performed before the utilization of streptomycin therapy.

G. ALLEN LEVY, M.D.

ANESTHESIA

Burstein, C. L., and Alexander, F. A. D.: Anesthesia for Thoracic Surgery. Management in an Army General Hospital Overseas. *Anesthesiology* 947 8 36.

This communication is based upon observations made during anesthesia for 1,165 consecutive operations within the chest, with an overall mortality of less than 0.2 per cent. The more important specific problems in management are discussed. Completion of the surgical mission may be contributed to by anesthesia which protects the patient from untoward reflex changes, ensures ample oxygenation and carbon dioxide elimination by adequate ventilation, minimizes annoying motion of intrathoracic viscera, and results in as little disturbance of normal physiologic function as possible.

A technique of anesthesia intended to fulfill these requisites has been evolved by the authors during the conduct of cases in a military hospital. This technique consisted of rapid induction with a relatively large dose of pentothal sodium. In patients who had suffered recent hemorrhage, or were poor risks for any cause, the size of this dose was markedly reduced. Intubation was performed with a large bore Magill endotracheal tube with inflatable cuff (attached to a Waters to-and-fro canister of soda lime and a bag). Anesthesia was maintained with nitrous oxide oxygen and ether supplemented by continuous manual reinforcement of automatic inspiratory efforts—compensated respiration. Various procedures to prevent untoward cardiocirculatory reflexes and peripheral circulatory depression were applied. This technique proved safe and satisfactory in the instances in which it was used.

The authors believe that the greatest single factor contributing to the success in these cases was the insistence upon absolutely rigid adherence to sound surgical practice, not the least part of which is teamwork which begets mutual confidence among all individuals concerned. MARY FRANCES POE, M.D.

Devision, T. C., and Letton, A. H.: Muscular Relaxation in Abdominal Surgery with the Use of Pentothal-Oxygen and Curare; Report of Over 600 Cases. *South. Surgeon* 947 23 15.

The results obtained by the authors at the Georgia Baptist Hospital, Atlanta, with the use of curare with pentothal-oxygen in abdominal surgery have been so gratifying that its use there is now surpassing that of other forms of anesthesia. The authors have compiled the pertinent facts in the cases of 600 major operations in which this method was used. For comparison, statistics were also compiled on a corresponding group of cases in which pentothal alone was used.

The drugs are administered by three way stop-cocks, and oxygen is given continuously. The addition of curare diminished the amount of pentothal used, by 19.3 per cent and was undoubtedly the big factor in reducing the length of postoperative sleeping. In a few cases there was a drop in blood pressure. Artificial respiration was not indicated in a single instance. Phlebitis did not occur in any case.

The authors prefer the synergistic effects of pentothal-oxygen-curare in abdominal surgery. The induction is rapid, the effects pleasant for the patient, postoperative complications are lowered, and the danger of explosion is minimized.

MARY FRANCES POE, M.D.

Beard, J. W.: Pentothal-Curare Mixture. 4 *anesthesiology* 947 89 75.

The author describes the preparation of pentothal curare mixtures for use in anesthesia. After numerous experiments with varying percentages of curare and combinations of buffers with the pentothal curare mixture the present formula was found most suitable: 2.5% per cent aqueous pentothal sodium, 18.3 c.c. and d-tubocurarine, 1.5 c.c. (150 units).

This mixture shows no precipitation for 14 days although the solution darkens with age. A freshly prepared solution of pentothal sodium is necessary to prevent the formation of a precipitate when higher concentrations of curare are used. Solutions over 12 hours old should be discarded. It is advisable to add the curare to the pentothal solution while it is being agitated, to avoid a precipitation at the point of contact of the two liquids.

In the opinion of the author, 5 to 7½ units of curare per cubic centimeter of solution is the correct concentration of curare. Pentothal curare anesthetics (alcoholic and aqueous) have been administered in more than 50 cases with varying degrees of success. The series includes the use of this mixture for patients on whom cholecystectomy, gastrectomy, colectomy, radical mastectomy and plastic operations have been performed and for passing an endotracheal tube preliminary to the administration of cyclopropane. One half to 1 c.c. of the mixture was intermittently injected intravenously as required to maintain adequate muscular relaxation and depth of anesthesia.

It was noted that less pentothal was required in the cases in which the mixture was used than in some cases in which no curare was added to the pentothal solution. The curare solution obliterates many of the troublesome reflex movements which are seen during pentothal anesthesia. The period of recovery is usually shortened following termination of the anesthetic. Prostigmine was administered to patients to counteract an overdose of curare. Induction of anesthesia and recovery of the patient were without untoward incident. Muscular relaxation was adequate in all cases. Severe laryngospasm was not encountered even though the patient coughed when the glottis was stimulated by the endotracheal tube. The average amount of solution injected preliminary to passing the tube was 10 to 15 c.c. of the mixture.

MARY KARP, M.D.

Smith S. M., Brown H. O., Toman J. E. P. and Goodman L. S.: The Lack of Cerebral Effects of d Tubocurarine. *Anesthesiology* 1947 8:1

No unanimity of opinion exists as to the central properties of curare. Animal experimentation can provide, at best, only a partial and indirect answer as to whether curare exerts a central depressant or analgesic action in man. Therefore, it was thought desirable to obtain the subjective report of a trained observer under the influence of curare alone and not undergoing a surgical procedure.

In a normal subject, a dose (500 mgm.) of d tubocurarine chloride at least two and one half times that required to cause complete respiratory paralysis failed to alter the electroencephalogram or to impair consciousness, memory or sensorium. Significant effects on systems other than skeletal muscle were also absent.

Neostigmine given in fairly large dosage greatly facilitated recovery from the curare-induced paralysis. Although 3.5 mgm. of neostigmine methylsulfate

were given intravenously within a period of less than 2 hours no significant muscular action on the gastrointestinal tract, urinary bladder or cardiovascular system was observed and atropine was not required. Curare is usually considered to have no direct blocking action on smooth muscle cells. The stimulant effect of neostigmine on the constrictor of the pupil and on the secretory glands was abundantly evident. Neostigmine had no discernible central effect on the nervous system and the electroencephalogram was not altered.

It is suggested that if curare is to be used properly as an adjunct in anesthesia its inability to depress the central nervous system be kept clearly in mind. Its sole action of value in anesthesia is to produce skeletal muscular relaxation by the peripheral paralytic effect on end plates of skeletal muscle cells. It should be employed only as an adjunct with agents capable of relieving pain and obtunding consciousness. Failure to appreciate the limitation of curare may bring this very valuable agent into undeserved disrepute.

MARY FRANCES FOX, M.D.

Dripps, R. D.: The Immediate Decrease in Blood Pressure Seen at the Conclusion of Cyclopropane Anesthesia: 'Cyclopropane Shock.' *Anesthesiology* 1947 8:75.

The etiology of the decrease in blood pressure not infrequently noted at the conclusion of cyclopropane anesthesia has been investigated. The usual sequence of events is as follows:

The blood pressure during anesthesia is elevated above the preoperative level. When the mask is removed both systolic and diastolic pressures decrease the rate and extent of the decline being variable. In those patients showing an immediate and precipitous fall in blood pressure the skin becomes clammy the pulse is of poor volume and emergence delirium is profound. It is in this condition that the term cyclopropane shock has been applied.

Certain facts seemed to fit together to provide a logical explanation for the phenomenon. It has been established that cyclopropane anesthesia is associated with a respiratory acidosis which is ascribed to the accumulation of carbon dioxide. Secondly it is known that sudden cessation of rebreathing is accompanied by a prompt decrease in the blood pressure level the diastolic pressure being decreased more than the systolic. Finally it has been demonstrated that loss of carbon dioxide is often associated with a diminution in blood pressure in the anesthetized man and animal. It is apparent that the buffer mechanisms are sufficiently active to maintain the nervous control of the cardiovascular system unless they are partially or completely inactivated by a depressant drug.

The hypothesis was thus formulated that the rise in blood pressure or the maintenance of circulation under cyclopropane anesthesia was related to carbon dioxide retention secondary to the respiratory depressant action of the drug. When the respiratory depressant was removed at the conclusion of the

anesthesia, an elevated carbon dioxide tension in the arterial blood would diminish and the blood pressure also would fall.

The results of clinical studies give evidence in favor of the hypothesis. The possibility has been considered that other physiological imbalances secondary to the closed system method of administration may be concerned in the postoperative decrease in blood pressure.

Certain practical considerations arise if this theory is proved correct. First, the nature and amount of the preoperative narcotic becomes important. Second, it is apparent that the sequence of events leading up to this postcyclopropane hypotension is more the fault of the anesthetist than the anesthetic. Third, some clinicians have learned to minimize this postcyclopropane decrease in blood pressure by utilizing semi-open techniques with rapid flows of nitrous oxide-oxygen during the last 5 to 15 minutes of a prolonged cyclopropane anesthesia. Fourth, it might be of interest therapeutically to attempt to control this hypotensive reaction by using carbon dioxide inhalations during the period of emergence from anesthesia. Treatment of this condition in the opinion of the authors, consists essentially of its prevention through maintenance of an adequate respiratory exchange.

MARY FRANCES FOX, M.D.

Loech, B. C.: Safety Measures in Anesthetics. *Canad. M. Ass. J.* 1947 56 28.

Explosions and fires have occurred in operating rooms due to the explosibility and inflammability of many of our most useful anesthetic vapors and gases.

Static sparks (more common in a dry atmosphere) form probably the greatest hazard. Common sense and alertness to the hazards are the best safeguards.

Characteristic of all presently available local anesthetic drugs is that an individual overdose produces tonic muscle spasms and possibly full-blown generalized convulsions. An intravenous barbiturate, sufficient to relax the muscles, is considered the best antidote, and may promptly allay the convulsions before the respiratory and heart muscles become affected. Pentothal sodium given intravenously in a 1% or 5 per cent solution is effective. Possibly intravenous curare may prove to be even more effective.

No spinal anesthetic is ever given without frequent blood pressure readings, or without a vasopressor drug at hand, in order that blood pressure may be maintained within reasonably normal levels throughout the operation. A very dilute solution of neosynephrine or methedrine intravenously is used. Adrenalin is avoided because of its reputed danger in association with cyclopropane, which is often used as a supplement.

The strength of pentothal sodium now recommended is 1% per cent for ordinary methods of use for the continuous intravenous drip technique, 0.3 per cent is satisfactory. The author stresses a few specific don'ts for pentothal safety.

Endotracheal intubation is a procedure that every anesthetist must master for such a maneuver has

been lifesaving. Whole blood transfusion should be anticipated and made ready for extensive procedures. Plasma should be constantly on hand both as an emergency substitute for blood and for conditions in which it is particularly indicated. Electrolyte solutions must be in generous supply and ready for immediate use. For long or serious operations, the author feels sure the happiest anesthetist is the one who has an intravenous drip running and his patient intubated, for he is then in a masterful position.

It is thought that curare is among the safety agents of the modern anesthetist's armamentarium, for it is a relatively safe agent which will produce complete muscular relaxation for a short period and can be safely repeated as needed. From the standpoint of safety it should be stated that the sometimes serious laryngospasm, which causes respiratory embarrassment, can be temporarily overcome by the use of curare.

Suction as a safety measure to the anesthetist has a value which can scarcely be overestimated.

Today anesthetists believe that unduly shallow or slow respirations usually need only the mechanical augmentation which can be easily supplied. The patient who has a good pulse, but whose respiratory movements, either by accident or by design, have ceased entirely can be adequately supported by the simple method called controlled respiration.

While falling circulation can usually be dealt with, actual cardiac arrest is quite a different matter and is usually irreversible. The generally advocated emergency measures are reviewed.

A recovery section probably is the best answer to the problem of early postanesthesia care the most dangerous period being that immediately following the patient's return to bed, when adequate supervision may be lacking.

MARY FRANCES FOX, M.D.

Schmidt, E.: Low Spinal Cord Injuries following Spinal Anesthesia. *Acta chir scand.*, 947 95 102.

From the time that spinal anesthesia was first used there have been reports of complications of the nervous system. Following a discussion of the pharmacology of the various spinal anesthetic drugs the author reviews the literature and presents the material which he has collected through questionnaires concerning complications of the central nervous system.

While reviewing this material the author encountered many studies of up to a few thousand cases in which there were no complications. This fact is mentioned as a counterbalance against the alarming series presented. Experimental studies show that tropacocaine, novocain, alypin, and stovaine in certain cases cause definite spinal cord lesions. The disturbances are either reversible or permanent. The injuries are located in the spinal cord and are most marked near the site of injection. Nerve roots and spinal ganglia are spared as a rule.

The author found in the literature reports of meningeal reactions following the use of most all of the local anesthetic agents. The reactions are usually

very mild and transient, and only in exceptional cases does the meningeal irritation reach an alarming degree.

Low lesions of the spinal cord usually manifest themselves through phenomena of irritation or loss of function. The symptoms may appear at once or may become noticeable only after days or months.

The author collected some valuable material as a result of his questionnaire sent to 121 hospitals. It was deduced that the number of spinal anesthetics used per year for the whole country of Sweden may be estimated at between 25,000 and 30,000. During the period from 1943 to 1945 there were 6 definite cases of severe postanesthetic injury—a frequency of about 0.01 per cent. Hypobaric percarine was used much more frequently than novocain, decaline or tropacaine.

The 6 cases of postanesthetic damage of the nervous system are reported in detail. The probable cause of injury to the spinal cord is the chemotoxic effect of the anesthetic. The effect on the myelin is proportional to the strength of the anesthetic solution as well as to the injected volume. Because so few people are affected there may exist a rare individual sensitivity.

In a few cases marked and severe pain appears during the injection of the anesthetic. In the event of severe pain it is strongly recommended that the injection be discontinued and that if possible the operation be postponed.

The advantages of a well given spinal anesthetic are still great and easily counterbalance the small risk of postanesthetic injuries. However according to the author the indications for spinal anesthesia should be more rigid. Another less harmful anesthetic should be substituted whenever possible.

EDITH EASON M.D.

Ballie H. Impending Death under Anesthesia.
Lancet, Lond., 1947: 1, 5.

Experience has taught that cardiac arrest can occur in any patient, with any anesthetic agent and any anesthetist. For obvious reasons, a general emergency surgeon is more often confronted with impending death under anesthesia than is the surgeon engaged in special branches.

Two fundamental conditions are segregated: blue asphyxia (primarily respiratory) and white asphyxia (primarily cardiac). The latter is far more serious. After 30 years' observation, the author has now abandoned expending time in the performance of artificial respiration and the injection of adrenaline into the ventricle. He recommends immediate cardiac massage when the heart stops. The current plan of action includes intermittent compression of the ventricles through the diaphragm within 15 minutes after the stoppage occurs. It appears that the early anxieties and later complications that follow temporary cardiac cessation are proportional to the length of time the organ is functionless.

The time limit for successful cardiac massage is a great deal longer in cases in which the heart has

ceased to beat after blue asphyxia, as the cerebral mechanism is not deprived of blood.

In sudden cases of vasomotor collapse when a pint or more of fluid must be put into circulation in a matter of minutes, injection by syringe (not by gravity) into the bone marrow is a method that has yet to be bettered. This method is advocated by the author for use in desperate crises.

MARY FRANCES POE, M.D.

SURGICAL INSTRUMENTS AND APPARATUS

Wynn S. K., and Macomber D. W.: Practical Points in Wolfe Graft Technique. *Surgery* 1947: 31, 86.

The authors review their experiences in over 100 cases in which they employed a thick graft of this type. Because this graft is more durable, shrinks less, and provides a better color match, they have elected the Wolfe graft whenever the defect has been not too extensive, the recipient area favorable enough, and the best appearance and greatest durability are desirable.

The choice of the donor site is most important when the defect is on the face. It is generally believed that the upper eyelid and postauricular tissues provide the most perfect quality and color matching for small facial defects, and for larger areas the lower neck or clavicular region is superior. The remaining defect is treated with undermining and closure, or by a split skin graft. The inside surface of the upper or lateral thoracic wall provides good quality skin but the color is less favorable.

Thigh skin provides a useful Wolfe graft. It is advocated that donor skin for a defect upon the dorsum of the nose may match much more accurately if a split graft is removed from the donor site and allowed to heal prior to the main operation. This gives the area an orange peel appearance and is especially important if the individual has enlarged pores. Usually 3 weeks following the removal of the thin graft, the full thickness graft can be cut to pattern from this natural appearing donor site.

Since the graft is nourished from the base rather than from the edges, its recipient bed must be clean and vascular. Gentle, firm and constant pressure should be maintained following the removal of stitches and the early dressings, for a period of 3 weeks or more.

It is believed that the Wolfe graft should be cut approximately 20 per cent larger, to allow for inevitable shrinking and to avoid tension at its periphery. The authors prefer to cut a pattern beforehand. When the graft is dissected from its donor site, every morsel of subcutaneous fat is removed from its under surface. In fact a bit of the corium is commonly removed in order to be certain. They stress the use of straight scissors, absolute hemostasis with nonabsorbable suture, the use of adrenalin solution locally and suturing with interrupted material. They favor pressure dressings with a pattern tied in place by sutures and covered by a large dressing if possible.

In considering eyebrow grafts they feel that the scalp graft for making an eyebrow is an exception to the rule that the free graft is utterly dependent upon its base, rather than its edges, for nutrition. Two or three long narrow grafts, placed side by side at intervals of 10 days or more result in survival of more hairs, especially if the knife blade is inserted into the donor area and drawn parallel to the hair shafts while taking the graft. It is a familiar fact that the hair or hair roots within the graft at the time of transfer usually are shed. Then a certain per cent of the follicles survive and produce new hair. It is noted that often more hairs survive near the borders of the graft and a higher percentage survive in a slender graft than in a wide one. Knowing that bold thinning on the deep side of this graft destroys many hair follicle bulbs, they find that less bold thinning and a narrower graft begets a greater per cent of viable follicles. These observations indicate that substantial nutrient reaches the graft from its side.

The postoperative care is meticulous. Face grafts are not dressed for 5 days unless necessary and the stitches are removed at that time. Elsewhere the dressing may be left undisturbed for 10 days or so. The mold made at the original operation is replaced

and pressure maintained for 3 to 4 weeks, until most of the shrinking has stopped and the graft is beginning to assume a natural color. By the end of 6 to 8 weeks, it is frequently possible to evaluate the success of the original grafting procedure and plan any corrective procedures.

Complications which may be noted at initial dressing, and a method of treating them are as follows:

1. Blebs on the graft. These should be opened, fluid expressed, and 20% mercurochrome applied.

2. Separation of the suture line. This should be reapproximated by strips of flamed adhesive.

3. Hematomas under the graft. If at the edge it is evacuated by simple expression and the edge reapproximated by adhesive. If not at the edge, it is best evacuated by a stab wound.

4. Serum under the graft. This is treated the same as hematomas.

5. Areas of necrosis. It is best to await separation, then remove by small scissors, and dress with a single ply fine mesh scarlet red gauze, over which the usual pressure dressing is reapplied.

6. A remote, unpredictable, and uncontrollable complication in some cases is pigmentation of the graft.

LEROY J. KILGORE, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Robbins, L. L. The Technique of Roentgenological Demonstration of Pulmonary Infarct. *Am J Roentg* 1946, 56 736

Contrary to experience elsewhere, pulmonary infarction constitutes one of the two most common postoperative complications at the Massachusetts General Hospital, Boston

Since pulmonary infarction often is the first sign of an impending massive fatal embolism, and in view of the fact that certain preventive measures are now available, an early roentgen demonstration of such a complication is important.

The author describes a technique of roentgen examination which permits an early diagnosis of pulmonary infarct. Unless the patient's condition forbids the examination is started by roentgenoscopy. This is done with a high kilovoltage approximately 85 to 89 kilovolts, and a low milliamperage, to save the skin from overexposure. After the infarct is located spot roentgenograms, similar to those of the gastrointestinal tract, are taken in at least two different projections with the same kilovoltage and a very short exposure. A posteroanterior roentgenogram is always advisable and if spot films cannot be made, lateral and oblique roentgenograms are of additional value.

If a patient is too ill for roentgenoscopy a ceiling floor mounted tube stand is of great value. The bed with the patient is pushed beneath this tube and a roentgenogram is made at 6 foot distance. Such a procedure is much better than a portable examination in the patient's sick room. The technique of exposure is along the same lines as for the spot films. A rotating anode, which provides a small focal spot is used with high milliamperage and short exposure. Merrill worked out a modification of Fuchs' technique establishing optimum kilovoltage for the part to be examined and variation of milliamperage-seconds with the size of the patient. The factors are expressed in the following table

TABLE I.—CHEST EXAMINATION

Fluor Chest	300 mA.		7 in. distance			
	Posteroanterior		Oblique		Lateral	
	CR.	SEC.	CR.	SEC.	CR.	SEC.
Small	9	1/50	3	1/50	16	1/5
Average	10-15	1/30	3-3.5	1/5	17-18	0/10
Large	15-20	1/20	3-3.5	1/5	18-	1/1
Range	30-	1/5				
	66 kv		75 kv		80 kv	

Roentgenograms taken with this technique are steel gray showing poor contrast but of distinct value

in diagnosing infarct. Bronchograms and laminograms have proven of little or no value

Differential diagnosis includes bronchopneumonia, metastatic malignancy and during the healing stage of the infarct linear shadows of atelectasis. If the infarction has produced a diminution in the size of the affected lobe the possibility of a primary carcinoma of the lung must also be considered

T LUCOTIA M.D.

Lindgren E. Roentgen Diagnosis of Arteriovenous Aneurysm of the Lung *Acta radiol.*, Stockh. 1946 27 585

For practical purposes, the term arteriovenous communications is used to include arteriovenous aneurysm cirroid aneurysm pulsating angiomas, and simple angiomas. The symptoms of these lesions are generally circulatory and local and they depend on the location of the abnormality. Central lesions generally lead to cardiac manifestations or sudden death. Peripheral lesions result in a gradual enlargement of the heart and dilation of the involved artery.

Three cases of arteriovenous aneurysm of the lung are reported. Two of these cases were diagnosed before operation surgery was not performed in the third case. The clinical findings were cyanosis clubbing of the fingers dyspnea sensations of weight or pain in the chest and hemoptysis.

The anatomopathological findings in arteriovenous aneurysm are classical in that the distended afferent artery and distended efferent veins are clearly seen. There is either a direct communication to one or several larger vessel trunks or a tangle of more or less distended vessels rather than capillaries. As the arterial pressure is transmitted to the malformed vessels and into the veins, these become increasingly dilated. Degenerative changes take place in the walls and eventually some of the vessels rupture. In time new pathological communications will be produced.

Roentgen findings reveal a broad band shaped density which is connected with the hilar vessels. In the periphery the latter communicate with one another. The vascular formations are more or less rounded and resemble tumors. The vessels lie in different planes this is best demonstrated in the lateral view or by fluoroscopy. The arteries are less distended than the veins and the aneurysm is most distended of all. Larger aneurysms may simulate tumors. Arteriovenous aneurysm communicates with the hilus and decreases in size with the Valsalva maneuver (forced expiration with the closed glottis). The Muller test increases the size of the aneurysm. In some instances it is necessary to distinguish an arteriovenous aneurysm from a tuberculous process other inflammations atelectasis and infarct. Calcification in the aneurysm was not observed by the author. Pulsation had been observed at the time of operation although not at the time of fluoroscopy.

Valuable adjuncts to the routine fluoroscopic roentgenographic studies are contrast visualization and laminagraphy. The author is of the opinion that the congenital arteriovenous communications do not give rise to cardiac enlargement.

MAURICE D. SACKS, M.D.

Ramos, A. G. P., Guitarte, A. I., and Bianchi, A. A.: Peritoneal Pneumoradiography in Gynecology (La neumoradiografía peritoneal en ginecología). *Bol. Soc. obst. gín. B. Aires* 946 25 196.

In gynecological problems, when circumstances prevent careful and complete diagnostic examination, peritoneal pneumoradiography is most helpful. It is a relatively simple procedure, causes a minimum of discomfort, and is free from major complications. It gives a good pelvic panorama.

This article gives the technique used by the authors and presents the case reports of 10 peritoneal pneumoradiographies and 5 hysterosalpingographies in combination with the pneumoradiographies.

Carbon dioxide was employed because it does not resorb as rapidly as oxygen or air.

Illustrations demonstrating the appearance of pathological conditions such as ovarian cysts, hydromyxoma, the pregnant uterus, as well as normal pelvic structures, are presented.

The authors consider the procedure definitive, and an extremely useful diagnostic adjunct in difficult gynecologic cases.

STEFANO A. ZIMMAN, M.D.

Belgrano V and Gardella, G.: Para-Articular Ossifications (Ossificazioni para-articolari). *Radiol. med. Milano*, 946, 31 43.

Twenty-three cases of post-traumatic para-articular ossification and 1 case following a medullary lesion with resulting paraplegia are reported by the authors. Four patients were younger than 30 years and among them was 1 boy 5 years old. The authors believe that according to the literature this was the youngest patient on record in whom a post-traumatic para-articular ossification occurred.

The ratio of contusions, dislocations, and fractures followed by ossification was 3 to 7 to 8.

In 4 cases the ossified tissue was removed and in 3 of them the macroscopic examination and histologic studies demonstrated a close relationship to the articular capsule which undoubtedly served as a source of bone formation. Post-traumatic para-articular ossification may be caused by a metaplasia of periosteum, ligaments, articular capsule, or other para-articular tissues. Such processes are stimulated by forced mobilization of the rigid articulation, passive movements, and rough massage.

Several conditions must be considered in the differential diagnosis. Para-articular ossification shows a trabecular structure in roentgenograms while calcifications cast a homogeneous shadow. Pictures taken in various directions may detect an origin from the bone suggestive of a hypertrophic callus, an osteosarcoma, or an exostosis. Para-articular ossification or so-called Pellegrini-Stieda's disease affects the el-

bow chiefly. Clinical symptoms may be absent, a calcareous or osseous structure is demonstrable, the condition is usually stationary, and the site of the changes is usually an articular ligament.

On the other hand regressive calcareous periartthritis, or Duplay's disease, is usually located in the shoulder region and creates a well defined clinical picture. The structure of the pathologic formations is amorphous, roentgenologically a rapid regression of the process may be demonstrated and the changes are located in the serous bursae in the insertion of tendons, and in para-articular tissues. Trauma cannot always be found in the history contrary to the findings in para-articular ossification.

The process reaches the "stage of maturity" when the roentgenographic shadow has sharp outlines and the density remains unchanged in pictures taken at certain intervals.

In 15 of 23 cases observed by the authors the condition was located in the elbow; in 5 in the knee; in 1 in the scapulohumeral articulation and in 1 case, at the ankle articulation. Only 1 patient belonged to the female sex. In 1 patient with a fracture of the ninth and tenth dorsal vertebrae followed by paraplegia, the roentgenograms disclosed para-articular ossifications in the paratrochanteric regions of both femurs and both knees.

Traumatic, chemical, and toxic factors have been attributed to para-articular ossification. Among the chemical factors, the decalcification of bone plays the main role. Patients with paraplegia usually suffer from an atony of the digestive tract with a resulting increase of the bacterial flora and absorption of endotoxic products. Hypercalcemia combined with trauma and such toxic products may cause the formation of new bone. Mechanical irritation of the edematous tissues has been accepted as a responsible factor by Freund.

Prophylaxis consists of gentle reduction of dislocations under deep anesthesia. The after treatment should consist of a gentle, nontraumatizing massage. Similar principles should be followed in the treatment of fractures. An infiltration of the affected ligaments with novocain, repeated whenever necessary is indicated in order to eliminate stimulation of hypertemia, organization of connective tissue, rarefaction of epiphyses and hypercalcemia. Anesthesia diminishes pains and allows early motions. Immediate immobilization of the injured limbs excludes irritation, alleviates pain, and accelerates absorption of extravasated blood. Slight compression for the same purpose is desirable. Diathermy improves the local circulation and accelerates absorption of the hematoma. X-ray therapy diminishes the tendency toward ossification but only in early stages.

As a rule, the "stage of maturity" is reached within 6 to 12 months after the injury. Surgical treatment is indicated not before this stage has been reached and only if limitation of motions is present and conservative therapy consisting of diathermy, gentle massage, and active mobilization has failed.

JOSEPH K. NARAY, M.D.

Cade Sir S., Scarff R. W., Golding, F. C., and Adams, S. B.: Discussion on Primary Malignant Tumors of Bone (Symposium) *Brit J Radiol.*, 1947 20 10

Cade has suggested the following simple grouping for the classification of bone sarcoma. The percent age, sites of origin and the radiographic findings are included

Osteogenic sarcoma (50%) Metaphysis rarefaction, sclerosis new bone formation, Codman's triangle and sunray spicules

Ewing's tumor (15%) Diaphysis sclerosis of cortex and medulla, onion peel new bone and patchy rarefaction

Multiple myeloma (30%) Medulla of diaphysis bone destruction no compensatory new bone formation

Parosteal sarcoma (15%) Diaphysis erosion from outside, osteolysis irregular calcification in soft tissue

To this group is added a fifth type which is nearly always benign in its clinical course

Osteoclastoma (20%) Epiphysis expansion and thinning of cortex, trabeculation no new bone formation

The balance between bone destruction and bone formation and the direction of the spread of tumor cells explain the variation in the x ray appearance. Sunray spicules are not always diagnostic of osteogenic sarcoma, nor are the onion peel layers an infallible sign of Ewing's tumor. These changes may be produced by nonmalignant lesions

Ewing's tumor is believed to be the most radio-sensitive type and parosteal sarcoma is believed to be the least sensitive type. Osteogenic sarcoma varies. Some sarcomas of this type are very sensitive others are resistant. Adequate irradiation may produce all or none of the following effects: progressive shrinkage of the tumor, recalcification of osteolytic lesions, resorption of abnormal bone, healing of pathological lesions, restoration of normal bone contour and histological evidence of arrest of neoplastic growth. These changes however are not permanent. Local recurrences are the rule rather than the exception.

Preoperative irradiation is always given in cases of osteogenic sarcoma. If the response is satisfactory amputation is postponed if no response is noted the irradiation is thought to have sufficiently inhibited the activity of the tumor so that the delay has in no way altered adversely the patient's life expectancy. I. M. Alchin, at Westminster Hospital, uses these factors: 200 kilovolts 2 mm. copper plus 1 mm. aluminum filter 300 roentgen divided daily tumor dose in a total average time of 5 weeks and total tumor dose of 3,000 roentgens

Ewing's tumor usually responds rapidly, though permanent regression is seldom achieved. Local recurrences are unusual if adequate irradiation has been given. Multiple metastases are the common final manifestation. In the absence of metastasis local recurrence is an indication for amputation.

Multiple myeloma is invariably fatal. Irradiation in small doses is the best palliative procedure for the relief of pain

Parosteal sarcoma is radioresistant. Surgical treatment is the method of choice. Postoperative irradiation to the stump is of value

Osteoclastoma may be treated by conservative surgery or by irradiation. Surgery is preferred (1) in young children when the tumor is in close proximity to the epiphyseal line (2) in tumors of moderate extent when the destruction of bone is limited and the cavity which is left by curetting is small (3) in tumors of the digits and (4) when the tumor has extended to the neighboring joint and irradiation will have to include articular and periarticular structures. Irradiation is indicated (1) in healthy adults (2) in all patients when the tumor is difficult of access and (3) in accessible tumors when the destruction of bone is great and pathological fracture is likely to follow curetting. The combination of curettement and irradiation is not advisable. Irradiation of postoperative recurrences is less successful than primary irradiation. The x ray therapy factors include 200 kilovolts 1.5 mm. of copper and 1 mm. aluminum filter. The daily skin dose for adults is 200 roentgens and for children 150 roentgens in an average time of 4 weeks. The total tumor dose for adults is 2,000 roentgens and for children, 1,200 roentgens. A second series of treatment is given after a period of 6 months and a third series after 18 months.

The role played by a single injury in the production of malignant disease has been largely abandoned. However Scarff states that there remains considerable evidence in favor of trauma as an etiological factor in sarcoma of bone, and angioendothelioma.

Although much has been written against the principle of biopsy, there is no real evidence to show an increased liability to metastasis following such a procedure. Histology is of great importance not only in diagnosis but also in the prognosis and treatment. Since the evidence against such a procedure is largely one of impression it is believed that the advantages leave no choice in the matter. In fact it is no more dangerous than palpation.

Scarff's classification of bone tumors omits parosteal sarcoma per se, as well as osteoclastoma, but includes infiltrating chondroma, extraperiosteal fibrosarcoma, medullary fibrosarcoma, angioendothelioma, and chordoma.

While most neoplastic lesions show some correlation between the histology and the subsequent behavior of the tumor, osteogenic sarcoma has thus far failed to behave in such a fashion. Some highly differentiated lesions showing rapid growth appear to have been completely eradicated by amputation while slow growing well differentiated lesions show no response either to surgery or x ray therapy. Periosteal fibrosarcoma and medullary fibrosarcoma offer a somewhat better prognosis than osteogenic sarcoma, hence should be classified separately.

The roentgen diagnosis of bone tumors is fraught with difficulties. Since the average roentgenologist

cannot hope to have a large personal experience, he must rely upon the literature. Goulding does not believe the latter to be too reliable. For example, giant cell tumors are supposed to originate in the epiphysis, yet he has never seen this tumor in the epiphyseal end of the bone until after the epiphyseal line has closed. In adolescents before closure of the epiphysis these tumors are found in the metaphysis. Moreover some giant-cell tumors bear a close resemblance to central osteolytic lesions such as cysts, medullary sarcoma, fibrosarcoma and, to a less extent, chondroma, fibroma, plasma-cell myeloma, and even adamantinoma. Many of these supposedly "trabeculated" tumors have no trabeculations. From the roentgenologist's viewpoint at least a period of observation and the clinical course of the lesions is often the only true indication of its nature. Almost all of the progress which may be made in exact diagnosis of the lesion is dependent upon the pathologist.

Adams has reported 4 cases of osteogenic sarcoma in which both pre- and postirradiation biopsies were performed. Diminution in the size of the tumor and histological evidence of radiosensitivity were shown in all 4 cases. Radiosensitivity was manifested by a marked relative absence of mitotic figures, many swollen nuclei and a greatly increased number of giant cells. Relief of pain is a most gratifying accompaniment of the irradiation. The swelling in cases of osteogenic sarcoma regresses much more slowly than in Ewing's tumor. R. B. LEWIS, M.D.

MISCELLANEOUS

Mitchell J. S.: Applications of Recent Advances in Nuclear Physics to Medicine. *Brit. J. Radiol.* 1946, 19, 481.

Recent advances in nuclear physics which led to development of the atomic bomb also provide a method for preparation of large amounts of radioactive isotopes. These should be used in medicine as follows: (1) Radioactive tracers in the study of metabolic processes, pharmacology, and therapeutics; (2) radiation therapy; (3) selectivity of certain isotopes for particular cells and tissues to serve as a therapeutic agent.

The "pile" serves as the source of radioactive isotopes. Tracers will undoubtedly lead to new developments in all branches of medicine. The isotopes used should have a reasonable half-life period. Concentration of the isotopes should not be too high. Phosphorus 32 and carbon 14 are two of the many isotopes being studied.

The pile may also serve as a source of gamma radiation in radiotherapy. Radiocobalt 60 with a half-life of 5.3 years and tantalum 185 with a half-life of 97 days are some of the isotopes being considered as a source of therapy.

Some isotopes have a selective concentration for certain tissues and may be used as a therapeutic agent. Phosphorus 32 has been used effectively in the treatment of leucemia, lymphosarcoma and polycythemia. Iodine 131 is used in thyroid diseases.

The cyclotron produces isotopes too, but in smaller numbers. However with the cyclotron it is possible to prepare radioactive isotopes in a state of high concentration. Cyclotron has the advantage over the "pile" in being able to prepare substances such as sodium 22 and iron 55. In some instances in which the isotope has a short half-life or the quantity desired is small it is more practicable to use the cyclotron.

The pile has the advantage of either being able to produce isotopes in large quantity or small amounts in high concentration. Then, too, fission products, such as iodine 131 can be used in radiation therapy. The "pile" cannot compete with the cyclotron as a source of fast neutrons whose high energies are used in the treatment of deep-seated malignancy. For practical purposes the "pile" has the following disadvantages: It is difficult to position patients; it is isolated; it produces whole body radiation which is a problem to control; and it is difficult to collimate the beam. MAURICE D. SACRE, M.D.

Hertz, S. and Roberts, A.: Radioactive Iodine in the Study of Thyroid Physiology. The Use of Radioactive Iodine Therapy in Graves Disease. *Ill. J. Surg.* 1946, 54, 474.

The authors' article is the seventh of a series. In the previously published 6 articles, they dealt with tracer studies of radioactive iodine in animal and human thyroid physiology and iodine metabolism. The present article is a 3 to 5 year follow-up report of a group of 39 patients with Graves' disease who were treated by internal irradiation with radioactive iodine.

The samples of radioactive iodine were obtained by deuterium bombardment of tellurium in the cyclotron. Over 90 per cent of the activity consisted of the 126 hour I^{131} and most of the remainder of the eight day I^{132} .

The dose, which was administered orally in the form of sodium iodide and without any preliminary iodine restriction, varied between 0.7 and 18 millicuries. In 19 cases a single dose, and in 20 cases multiple divided doses were given. In order to insure maximum collection in the thyroid the total iodide administered was kept below 5 milligrams of iodine.

It was found early that the maximum excretion of the radioiodine occurred in the urine during the first 72 hours. A quantitative determination of the radioactive iodine content of the carefully collected (iced and cooled) urine, therefore, gave an indirect estimate of the thyroid retention of the radioactive iodine. In a few cases external gamma ray counter measurements were also made.

The administration of the radioactive iodine was followed within from 1 day to several weeks by routine iodination of the patients with a saturated solution of potassium iodide given in doses of minima twice a day. This was continued, as a rule, for a period of 3 to 4 months until an essentially normal basal metabolic rate was obtained. A rise of the basal metabolic rate upon cessation of the iodination was considered as failure of the radioactive iodine therapy.

An attempt was made to express the radiation dose in the equivalent roentgen unit by applying the following formula

$$\text{Radiation (in roentgen units)} = \frac{10,000 \text{ (Dose of } I^{131} \text{ in mc) (fractional uptake in thyroid)}}{\text{weight of thyroid in grams}}$$

For I^{131} the constant 10,000 is replaced by 117,000. Thus, for I^{131} a net collection of 3 millicuries in a thyroid of 30 grams weight will give a total of 1,000 roentgens in decaying to zero. The initial rate of such irradiation is 55 roentgens per hour. For I^{131} it is only 3.6 per hour. However, an error of 50 per cent or more may be expected.

The results obtained in all 29 cases are summarized in tables. The treatment was considered a failure in 9 cases; the remaining 20 patients were apparently cured. Of the failures, 5 patients were subsequently operated upon and all developed postoperative hypometabolism.

The following clinical considerations are important (1) there should be no previous iodine therapy or if such therapy has already been undertaken it should be stopped for a period of at least 1 month to allow maximum uptake of the radioactive iodine (2) availability for close follow-up (3) routine iodization starting from 1 to 3 days after the administration of the radioactive iodine and (4) large goiter with secondary involuntal changes should be submitted to surgery on a purely mechanical basis.

In patients receiving radioactive iodine therapy, a short period of hospitalization is necessary for the usual preliminary clinical studies and the administration of the isotope. After that the patient is fully iodinated and released to be followed up as an ambulatory case.

The conclusion is drawn that radioactive iodine when given in doses of 5 to 25 millicuries to uniodinated patients with Graves' disease possessing goiters of 60 to 75 milligrams, produces a cure in about 80 per cent of the cases.

T. LEVITT, M.D.

cannot hope to have a large personal experience, he must rely upon the literature. Goulding does not believe the latter to be too reliable. For example giant cell tumors are supposed to originate in the epiphysis, yet he has never seen this tumor in the epiphyseal end of the bone until after the epiphyseal line has closed. Cyclotron has the advantage over the "pile" in being able to prepare substances such as sodium 22 and iron 55. In some instances in which the isotope has a short half-life or the quantity desired is small, it is more practicable to use the cyclotron.

The pile has the advantage of either being able to produce isotopes in large quantity or small amounts in high concentration. Then, too, fission products such as iodine 131 can be used in radiation therapy. The pile cannot compete with the cyclotron as a source of fast neutrons whose high energies are used in the treatment of deep-seated malignancy. For practical purposes the "pile" has the following disadvantages: it is difficult to position patients; it is isolated; it produces whole body radiation which is a problem to control; and it is difficult to collimate the beam.

M. Urick D. Swann, M.D.

Hertz, S., and Roberts, A.: Radioactive Iodine in the Study of Thyroid Physiology. The Use of Radioactive Iodine Therapy in Graves' Disease. *West. J. Surg.* 94 6 474.

The authors' article is the seventh of a series. In the previously published 6 articles, they dealt with tracer studies of radioactive iodine in animal and human thyroid physiology and iodine metabolism. The present article is a 3 to 5 year follow-up report of a group of 29 patients with Graves' disease who were treated by internal irradiation with radioactive iodine.

The samples of radioactive iodine were obtained by deuterium bombardment of tellurium in the cyclotron. Over 90 per cent of the activity consisted of the 12.6 hour I^{131} and most of the remainder of the eight day I^{130} .

The dose, which was administered orally in the form of sodium iodide and without any preliminary iodination, varied between 0.7 and 28 millicuries. In 10 cases a single dose, and in 10 cases multiple divided doses were given. In order to insure maximum collection in the thyroid the total iodide administered was kept below 1 milligram of iodine.

It was found early that the maximum excretion of the radiiodine occurred in the urine during the first 72 hours. A quantitative determination of the radioactive iodine content of the carefully collected (iced and corked) urine, therefore, gave an indirect estimate of the thyroid retention of the radioactive iodine. In a few cases, external gamma ray counter measurements were also made.

The administration of the radioactive iodine was followed within from 1 day to several weeks by routine iodination of the patients with a saturated solution of potassium iodide given in doses of minima twice a day. This was continued, as a rule for a period of 2 to 4 months until an essentially normal basal metabolic rate was obtained. A rise of the basal metabolic rate upon cessation of the iodination was considered as failure of the radioactive iodine therapy.

An attempt was made to express the radiation dose in the equivalent roentgen unit by applying the following formula

$$\frac{10,000 \text{ (Dose of } I^{131} \text{ in mc) (fractional uptake in thyroid)}}{\text{weight of thyroid in grams}}$$

$$\text{Radiation (in roentgen units)} = \frac{\text{weight of thyroid in grams.}}$$

For I^{131} the constant 10,000 is replaced by 117,000.

Thus for I^{131} a net collection of 3 millicuries in a thyroid of 30 grams weight will give a total of 1,000 roentgens in decaying to zero. The initial rate of such irradiation is 55 roentgens per hour. For I^{125} it is only 3.6 per hour. However, an error of 50 per cent or more may be expected.

The results obtained in all 9 cases are summarized in tables. The treatment was considered a failure in 9 cases, the remaining 20 patients were apparently cured. Of the failures 5 patients were subsequently operated upon and all developed postoperative hypometabolism.

The following clinical considerations are important (1) there should be no previous iodine therapy, or if such therapy has already been undertaken it should be stopped for a period of at least 1 month to allow maximum uptake of the radioactive iodine (2) availability for close follow up (3) routine iodioization starting from 1 to 3 days after the administration of the radioactive iodine and (4) large goiter with secondary involutions changes should be submitted to surgery on a purely mechanical basis.

In patients receiving radioactive iodine therapy a short period of hospitalization is necessary for the usual preliminary clinical studies and the administration of the isotope. After that the patient is fully iodinated and released to be followed up as an ambulatory case.

The conclusion is drawn that radioactive iodine when given in doses of 5 to 25 millicuries to uniodinated patients with Graves disease possessing goiters of 60 to 75 milligrams produces a cure in about 80 per cent of the cases.

T. LEUCUTA, M.D.

cannot hope to have a large personal experience he must rely upon the literature. Goulding does not believe the latter to be too reliable. For example, giant cell tumors are supposed to originate in the epiphysis, yet he has never seen this tumor in the epiphysis of the bone until after the epiphysal line has closed. In adolescents before closure of the epiphysis, these tumors are found in the metaphysis. Moreover, some giant-cell tumors bear a close resemblance to central osteolytic lesions such as cysts, medullary sarcoma, fibrosarcoma and, to a less extent, chondroma, fibroma, plasma-cell myeloma, and even adamantinoma. Many of these supposedly "trabeculated" tumors have no trabeculations. From the roentgenologist's viewpoint at least a period of observation and the clinical course of the lesions is often the only true indication of its nature. Almost all of the progress which may be made in exact diagnosis of the lesion is dependent upon the pathologist.

Adams has reported 4 cases of osteogenic sarcoma in which both pre- and postirradiation biopsies were performed. Diminution in the size of the tumor and histological evidence of radiosensitivity were shown in all 4 cases. Radiosensitivity was manifested by a marked relative absence of mitotic figures, many swollen nuclei and a greatly increased number of giant cells. Relief of pain is a most gratifying accompaniment of the irradiation. The swelling in cases of osteogenic sarcoma regresses much more slowly than in Ewing's tumor.

Mitchell, J. S.: Applications of Recent Advances in Nuclear Physics to Medicine. *Bull. J. Radiol.* 1946 19:481

Recent advances in nuclear physics which led to development of the atomic bomb also provide a method for preparation of large amounts of radioactive isotopes. These should be used in medicine as follows: (1) Radioactive tracers in the study of metabolic processes, pharmacology, and therapeutics; (2) radiation therapy; (3) selectivity of certain isotopes for particular cells and tissues to serve as therapeutic agent.

The "pile" serves as the source of radioactive isotopes. Tracers will undoubtedly lead to new developments in all branches of medicine. The isotopes used should have a reasonable half of life period. Concentration of the isotopes should not be too high. Phosphorus 32 and carbon 14 are two of the many isotopes being studied.

The "pile" may also serve as a source of gamma radiation in radiotherapy. Radioisotopes with a half life of 5-3 years, and tantalum 182 with a half life of 97 days are some of the isotopes being considered as a source of therapy.

Some isotopes have a selective concentration for certain tissues and may be used as a therapeutic agent. Phosphorus 32 has been used effectively in the treatment of leukemia, lymphosarcoma, and polycythemia. Iodine 131 is used in thyroid diseases.

The cyclotron produces isotopes too but in smaller numbers. However, with the cyclotron it is possible to prepare radioactive isotopes in a state of high concentration. Cyclotron has the advantage over the "pile" in being able to prepare substances such as sodium 22 and iron 55. In some instances in which the isotope has a short half life or the quantity desired is small it is more practicable to use the cyclotron.

The pile has the advantage of either being able to produce isotopes in large quantity or small amount in high concentration. Then, too, fission products such as iodine 131 can be used in radiation therapy. The pile cannot compete with the cyclotron as a source of fast neutrons whose high energies are used in the treatment of deep-seated malignancy. For practical purposes the pile has the following disadvantages: it is difficult to position patients; it is isolated; it produces whole body radiation which is a problem to control; and it is difficult to collimate the beam.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Cameron G. R.: Sudden Shifts of Body Fluids.
Proc. R. Soc. M. Lond. 1946 40

When a highly irritant liquid such as lewisite or mustard gas is dropped on the skin, a blister forms in a few hours as a result of the localized outpouring of blood plasma from the vessels of the affected part, detaching the avascular epidermis from the underlying vascular dermis. Previous investigations suggested that damage to the skin liberated proteolytic enzymes which were responsible for loosening of the basement membrane.

Such injury also produces a systemic circulatory upset, manifested by a decline in the plasma volume as estimated by photometric methods. If this state is sufficiently severe, death from 'shock' may ensue. Other associated changes are a rise in hemoglobin percentage, red cell count, and packed cell volume (hematocrit per cent) indicating a concentration of blood. The plasma-like fluid collects in the irritated tissues and produces an edema. The diminished circulating plasma volume and plasma proteins result in a functional renal upset with a consequent elevation of the blood urea level. A mild secondary anemia, as a rule, also occurs.

Irritating gases, such as phosgene, lewisite, and mustard vapor when inhaled, present a picture of local fluid loss similar to that described above. This results in pulmonary edema with acute mechanical asphyxia. Phosgene as such is not absorbed into the blood and therefore does not lead to serious systemic complications through its inherent chemical properties. Thermal burning produces the same disturbance in a more rapid manner as does the subcutaneous injection of large amounts of a hypertonic solution of glucose or saline. Thus, no matter how it is induced, acute anhydremia leads to the picture described above.

By cannulating the lymphatics of the involved area, and by determining the thoracic duct flow, it was found that some of the lost fluid and protein is returned to the circulation by way of the lymphatics. This form of compensation is of limited value and may even be deleterious by introducing harmful chemicals into the blood stream.

The rapid appearance in the injured tissues of a fluid rich in proteins signifies that the filtration membrane (capillary wall) had let through these large molecules in a quite unusual fashion. This was corroborated by experiments showing that after the application of lewisite or mustard gas to the skin, the capillaries become more permeable to a dye such as T 1824 which combines with plasma albumin.

The author believes that Menkin's leukotaxin and the histaminelike substance of Lewis, produced in tissues damaged by mustard gas, are no doubt the intermediaries bringing about the capillary wall

change which underlies increased permeability for plasma proteins. Anoxia increases the permeability of capillaries, as shown by Landis and Drinker.

Whether the alteration is a physical or chemical one in the surface membrane of the living endothelial cells of the vessels, or a loosening of the cement substance which binds together these cells, and whether living processes are concerned is all conjecture. The remarkable studies of Peters and Dixon on enzyme chemistry and chemical warfare agents have opened up a new way of approach to the permeability problem which may bring the solution.

DAVID H. LYNN, M.D.

Melman, E. P.: Concerning the Erythric Form of Traumatic Shock. *Fractures* Dec. 1946, No. 9, 643.

Experimental work on induced shock in animals and the many observations of injury on the field of battle have enabled the author to differentiate two different manifestations of primary shock: the erythric and the torpid forms. The injured man with the erythric form of primary shock is excited and pale, and he complains of the discomfort of his position and the pain in his wound. Nevertheless, despite hinge wounds of the organs he struggles to get up from the litter on which he has been placed and continuously beseeches the attendants to bring him to the dressing stations or to evacuate him further to the rear. Some of these patients refuse the help of the hospital corps and come by themselves for treatment. At the dressing station the discrepancy between the severity of the wound and the comparatively satisfactory general condition of the patient is at once noted. The pulse is of good quality and normal rhythm, and the blood pressure is good. Because of this the patient may be misjudged and denied the antishock measures which may save his life.

The author believes that this form of shock occurs more often than is generally admitted, since most of the observations come from the divisional hospitals where the wounded are received relatively late after receiving the injury. He stresses the need for the military doctor to pay more attention to this form of manifestation in order that the patient receives the necessary antishock treatment before the irreversible changes occur in the vital centers which will bring on the torpid form of shock manifestation and end in death.

A remarkable instance is cited of a soldier wounded in the abdomen by shell splinters, with prolapse of the intestines through the anterior abdominal wall, who refused the help of the sanitary corps, swam the river separating the two lines of battle and replacing his water soaked intestines, ran along under cover of the river bank, avoiding everyone he met until he reached, on foot, the divisional headquarters. There he kept righting himself to a sitting posture on the fit

ter on which he was placed and with glittering eyes, pale face and dry tongue kept close watch on the doctors, refusing operation until suddenly he sank back half unconscious with cold sweat, cyanosis of the visible mucosa and falling blood pressure and rising pulse. Blood transfusion, intravenous fluids, morphine, camphor and caffeine improved his condition and immediate midline laparotomy under local anesthesia, with removal of huge quantities of bloody fluids, metallic splinters with parts of bullet casings, and some entire percussion caps (the shell splinter had struck the patient's bullet pouch) with suture of the numerous holes in the small intestinal loops and in the sigmoid colon was carried out. Before the abdomen was closed streptocidal albumin powder was applied and 750 c.c. of conserved blood was given by transfusion. Following the operation the patient slept for 10 hours.

The postoperative ileus was combated by gastric lavage, syphonoclysis, glucose infusions, and calcium, sodium chloride, and urotropin. During the 10 day period of recovery more than 40 liters of normal saline solution and 0.8 per cent streptocidal solution were given. After 17 days at the field hospital the patient was evacuated to the rear in good condition and a month later he was reported as completely healed and in good health.

JOHN W. BRENNAN, M.D.

Hessner H. The Operation as Trauma. Reflections Concerning the So-Called Postoperative Illness (Die Operation als Trauma. Untersuchungen ueber das Wesen der sog. Postoperativen Krankheit). *Helvet. chir. acta*, 1946 13 167.

The author reviews the so-called postoperative illness which was first described as an entity by Leriche in 1933. He reviews all of the effects of an operative intervention on the various systems of the body economy, the symptoms of these effects and the cause as well as the possible correction of these effects. In considering these he calls attention to the various effects the operation may have upon pre-existing diseases of these organs as, for example, the effect of operations upon patients who have coronary heart disease, absolute or relative. On the other hand he also calls attention to the effects of the operative procedure upon the normal system.

The effects are mediated both through the vegetative nervous system and through changes in the metabolic and chemical processes caused by the operative intervention and anesthetic. Both psychic and physical trauma are active in the usual operative procedure so that all of the factors active in a traumatic experience are also existent in a planned surgical procedure. The author calls attention to the fact that the shock state which follows trauma is identical with that following a planned operative intervention. The difference lies in the fact that, in the latter case, the surgeon has the opportunity of studying all of the factors productive of traumatic shock and thus may be able to either obviate or at least, to minimize them.

The complete study of the patient and the planning of the operative procedure, not alone as an attack upon an organ but as an approach to a generalized disturbed physiology should obviate the so-called postoperative illness. The evaluation of all of the patient's reactions, the status of the function of the various bodily systems and the carefully planned anesthetic sequence are prerequisites for this. A thorough study of the status of all of the body's chemical balance and a knowledge of the effects of the surgical operation should almost completely outline the care which will be needed. Thus a study of the body fluids, electrolytes, and proteins, as well as of the red blood cells is important and measures for their replacement should be at hand in any well planned intervention. The evaluation of the cardiac status, the renal status, and the supply of adequate amounts of oxygen is recommended by the author.

WILLIAM C. BECK, M.D.

Hamilton T. R., and Angevine, D. M.: Fatal Pulmonary Embolism in 100 Battle Casualties. *Mil. Surgeon* 1946 99 450.

A survey was made of 1,065 autopsies on cases in which battle wounds had recently been sustained. It was found that in 66 or 6.19 per cent of these, death was due to pulmonary embolism.

A possible value of an analysis of battle casualties is the absence of such usually plaguing variables as age and previous or intercurrent disease since all of the patients have presumably been physically fit soldiers.

When an individual is lying on his back the increased compression of the left iliac vein by the arterial trunk (right iliac, middle sacral, and left hypogastric arteries) has a direct influence in slowing up the blood stream and explains the well known frequency of thrombosis in the left lower limb.

One hundred cases of fatal pulmonary embolism in battle casualties are reported.

Venous stasis, caused most frequently by immobilization, appears to be the most important factor in the production of phlebotrombosis.

Pulmonary infarcts were located predominantly on the right side and in the lower lobes.

The prevalence of venous thrombosis on the left side of the body did not have a direct relationship to trauma which occurred more frequently on the right side.

JOSEPH GASTER, M.D.

Heston, W. E.: Path of Gene Action in Mammary Tumor Development in Mice. *J. Nat. Cancer Inst.*, 1946, 7 79.

Gene, i.e., chromosomal control of mammary cancer in mice is considered as it operates along the following three action paths: (1) influence over the nonchromosomal milk agent; (2) influence over the extra-chromosomal hormonal action; and (3) the control of mammary tissue susceptibility.

Though the milk factor is known to exist by reason of its influence it has not been isolated and its nature is totally unknown.

Venous stasis, caused most frequently by immobilization appears to be the most important factor in the production of phlebothrombosis.

Pulmonary infarcts were located predominantly on the right side and in the lower lobes.

The prevalence of venous thrombosis on the left side of the body did not have a direct relationship to trauma which occurred more frequently on the right side.

JOSEPH GASTEN, M.D.

Heston W E.: Path of Gene Action in Mammary Tumor Development in Mice. *J Nat. Cancer Inst.* 1946, 7 79.

Gene, i.e., chromosomal, control of mammary cancer in mice is considered as it operates along the following three action paths: (1) influence over the nonchromosomal milk agent; (2) influence over the extra-chromosomal hormonal action; and (3) the control of mammary tissue susceptibility.

Though the milk factor is known to exist by reason of its influence, it has not been isolated and its nature is totally unknown.

Likewise estrogen production assay techniques permitting the required measurements for this influence are nonexistent.

There are differences in the response of different strains of mice—in their susceptibility to mammary tumors in their response to the milk factor and in their response to hormonal stimulation.

Alteration of genetic constitution will apparently eliminate the milk factor influence producing mammary tumor alter the mammary tumor incidence manifested through hormonal stimulation, and result in differences in susceptibility of mammary tissue to tumor formation.

Statistical evidence suggesting genic control of these influences is presented.

Since (1) there is no direct yardstick against which each influence can be measured independently of others, and (2) individual gene pattern alterations associated with changes of the influences are not mapped, direct proof of gene control over these action paths is not now possible. FRANK B. QUEEN, M.D.

Shimkin M. B., Wyman, R. S., and Andervont B.: Mammary Tumors in Mice following Transplantation of Mammary Tissues. *J. Nat. Cancer Inst.*, 1946, 7 77

Young male C3H strain mice freed of the milk agent were transplanted with mammary tissue from C3H virgin females not freed of the milk agent, and a cholesterol pellet containing 0.4 mgm. (100%) of diethylstilbestrol subcutaneously implanted to furnish adequate estrogenic stimulation for mammary tissue development.

In 90.4 per cent of the 67 mice surviving 8 months or longer mammary tumors developed. Only one of these arose at the site of the mammary transplant.

Thus an attempt to develop tumors in transplanted mammary tissue in mice failed, but a number of interesting implications were elicited.

It is postulated that sufficient milk factor was carried over in the transplant to cause the incidence of tumors to increase from the theoretically calculated expected normal of 3.5 per cent to 50 per cent incidence. C3H male mice not lacking the milk factor under the conditions of the experiments would be expected to develop 73 per cent tumor incidence.

There is no explanation for the failure of development of carcinoma in the transplanted mammary tissues (which in all cases survived).

FRANK B. QUEEN, M.D.

Shimkin M. B., and Wyman, R. S.: Mammary Tumors in Male Mice Implanted with Estrogen-Cholesterol Pellets. *J. Nat. Cancer Inst.* 1946, 7 71

The relationship between the dose of three estrogens, diethylstilbestrol, estradiol, and triphenylethylene, under conditions of continuous absorption and mammary tumor response in male mice of C3H strain is reported.

Cholesterol pellets containing a concentration of 0.5 to 30 per cent of diethylstilbestrol, 1 to 50 per cent

estradiol, and 10 to 50 per cent of triphenylethylene were subcutaneously implanted into one month old mice. Approximately 30 to 40 mice were used for each series (total, 461). The mice were observed usually until tumors developed, or until natural death. No tumors developed in mice receiving triphenylethylene.

From 2.5 to 86.6 per cent of mice subjected to the continuous influence of diethylstilbestrol developed tumors in from 16.8 months average time with the lower dose, to 6.0 months with the highest dose. With estradiol, from 3.5 to 77.3 per cent developed tumors, the time range varying from 0.3 months with the smaller doses to 5.9 months with higher doses. Thus there is a correlation between the concentrations of both diethylstilbestrol and estradiol and the incidence of mammary tumors as well as with the time required for their appearance. Estradiol appears to be the more potent of the two.

The recovered pellets were weighed and the effective dose of estrogen required for tumor induction calculated. Two micrograms of each sufficed to produce mammary adenocarcinoma in 5 per cent of the mice. The absorption necessary to produce tumors in 50 per cent of mice (TD₅₀) is computed at 4 to 10 micrograms for estradiol, and between 20 to 40 micrograms for diethylstilbestrol.

There is no predilection for the occurrence of the tumor near the site of estrogen implantation. There appears to be a correlation between the appearance of multiple mammary adenocarcinoma with the larger doses of estrogen.

The urinary excretion of estrogens in female mice is 0.05 to 0.1 micrograms per day. Thus, the TD₅₀ dose of estradiol and diethylstilbestrol for male mice is roughly equivalent to the normal urinary excretion in female mice during 100 to 500 days, respectively. I.e., the carcinogenic dose for male mice is well within the range of concentrations physiologically elaborated by normal females of the species.

The absence of hepatomas in the estradiol and diethylstilbestrol treated mice up to the age of 10 months is of interest. Normally male C3H mice from 11 to 19 months of age show a 25.8 per cent incidence of hepatomas and female mice of this strain in this age group show an incidence of 5.7 per cent. After 19 months some hepatomas did appear—an incidence of approximately 11 per cent in the diethylstilbestrol treated mice of 21 per cent in the estradiol treated mice, and 18 per cent in the triphenylethylene treated mice. It is suggested that "the later appearance and lower incidence of hepatomas in this experiment may be an effect of estrogenation."

FRANK B. QUEEN, M.D.

Shabad, L. M.: Trends in Cancer Research in the USSR. *Am. Rev. Soviet Med.* 1946, 4 66

The author reviews, as the title indicates, the important developments in cancer research in the USSR. He states that in the USSR, extensive surgery is practiced on cancer. Petrov and his associates at the Leningrad Oncologic Institute have done extensive pioneer work on gastric resections, new surgical methods

for cancer of the esophagus, and on electrosurgery of the stomach. X-ray treatment of bronchogenic carcinoma has been improved by the method of Dillon because the therapy is given through numerous skin sectors converging on the cancer which requires exact topical diagnosis.

Tumor research has followed the same general lines as in the United States of America. The synthesis of various derivatives of 1,2 benzantracene and their carcinogenic activity have been studied. Amino-azo-compounds have been rather extensively studied and a transplantable hepatoma was developed in mice. Dispersion of chemical carcinogens has been studied by measurements of fluorescence. A colorimetric method for determination of amino-azo-carcinogens has also been developed. This is applicable to tissues and fluids.

One interesting experiment reported deals with the influence of inflammation on carcinogenesis. 3,4,8,9 dibenzopyrene painted with turpentine solvent lowered the incidence of carcinoma formation in mice according to the theory of an "antiblastic" function in acute inflammation. Experiments designed to test the relationship of chemical carcinogenic activity to toxicity disclosed no correlation.

Endogenous carcinogens have been studied and as in this country substances having carcinogenic activity were extracted from the liver, bile, lungs, and occasionally from the urine of patients dying with malignant neoplasms. The nature of these endogenous carcinogens is unknown but it is concluded that they are not cholic or desoxycholic acid.

A synergistic action between exogenous and endogenous carcinogens is postulated. Active carcinogenic factors have been studied without definite conclusions.

Considerable attention has been devoted to virus tumors. The author considers that the agent of "virus" growth may be an endogenous chemical substance of cellular origin. Experiments cited permit no conclusion either way.

A complement fixation test aiding in the recognition of the milk factor in spontaneous mammary carcinoma of mice (strain A) and in an inoculated growth (strain MAF) is also reported. The author questions whether the milk factor is a virus or an endogenous chemical produced by the epithelial cells of the mammary gland.

The role of heredity has been studied in some detail in 156 pairs of human twins, at least one of whom developed cancer. Of 31 pairs of monozygotic twins, 27 presented only one of the pair with cancer while both twins in 4 pairs suffered from cancer (22% similarity). In 95 pairs of dizygotic twins, both members were affected in 13 pairs (13.7%) an incidence close to that of monozygotic twins. This leaves no foundation for assuming a general hereditary susceptibility to neoplasia in man. However the neoplasia is similarly located much more frequently in monozygotic twins than in dizygotic twins. Thus, the reactivity of tissues to the carcinogenic agent may depend directly upon genetic factors.

The studies in carcinogenesis have shown that some polymorphocellular sarcomas are of myogenic origin

and that these malignancies tend to slow down growth and revert to the primary normal tissue. Nuclear studies show a typical mosaic consisting of translocations of various chromosomes in malignant cell nuclei.

The antitumoral cytotoxic serum of Bogomolets was tested for the control of metastases and relapses after surgical excision of cancer. Results are not mentioned although it is stated that the use of this serum in animals (mice) reduced the development and incidence of methylcholanthrene tumors.

The section of certain nerves is said to modify the growth of experimental tumors and the localization of metastases.

The anticancer properties of blood and spleen (antiblastic properties) studied in mice with early carcinoma were found to be absent in the serum of cancer patients but they were present in that of healthy men.

The mitogenetic property of blood and tissues was studied from a diagnostic viewpoint. This mitogenetic radiation of the blood was lost in cancer cases because of a special substance called "extinguisher." 'Extinguisher' also appears in the blood of mice following the subcutaneous implantation of carcinogens.

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Curley F. J. and Aycock, W. L.: *The Effect of Stilbestrol on Resistance to Experimental Polymyositis*. *Endocrinology* 1946, 39, 414.

In previous experiments it had been shown that the resistance of castrated monkeys to intranasal instillation of the virus of polymyositis was enhanced by the intramuscular injection of estrogenic hormone. The present experiments were performed to determine the conditions under which this enhancement occurred. They did not in themselves afford any indication as to whether the mechanism of resistance set up by the administration of estrogen lay in a physiological blockade of the nasal mucosa (in the fashion of a chemical blockade produced by local application) or in some more deep-seated structure, as, for example, the central nervous system itself.

In the first group of experiments normal immature monkeys were treated with stilbestrol, testosterone propionate or both, and were then subjected to intranasal instillations of monkey polymyositis spinal cord emulsion. In the second group the experiments were repeated, but in these animals castration had been performed a weeks before the beginning of hormone injections. The stilbestrol-treated animals which failed to succumb were later inoculated intracerebrally along with normal monkeys as controls. In the third group castrated female monkeys were treated with reduced amounts of stilbestrol and then inoculated intranasally along with the controls. The monkeys which survived were inoculated intracerebrally.

The treatment of normal monkeys with stilbestrol or testosterone produced no increase in resistance, while stilbestrol treated castrates showed a marked

increase in resistance to intranasal instillations of the virus. Testosterone alone had no protective effect. Stilbestrol treated animals which had resisted repeated intranasal instillations of virus, although kept on stilbestrol, showed no increased resistance to subsequent intracerebral inoculation.

That repeated intranasal instillations of virus under the protection of stilbestrol did not serve to immunize is indicated by the fact that subsequent intracerebral inoculation resulted in experimental poliomyelitis in all animals so treated. That the intracerebral inoculations were not too severe a challenge as a test for immunity is suggested by previous studies demonstrating the resistance of intracerebrally immunized monkeys to similar intracerebral inoculations.

DAVID H. LYNN, M.D.

Cherkasov A. V.: Peculiarities of the Disease Course in Recurrent Typhus in Children. *Pediatrics, Akusherstvo i Ginekologiya*, 1946 No. 2, p. 8.

Cherkasov noted numerous cases (26 per cent) in which there were more than 3 recrudescences and remissions in the course of the illness. Four and one-half per cent of the patients had recurrence of fever following apyretic periods. Not infrequently there were disturbances in the usual course of the disease. In 11 per cent the second attack was longer than the first. In 7 per cent the third attack was longer than the second. In 6 per cent the second period of apyrexia was of shorter duration than the first, and in 4 per cent the two periods of apyrexia were of equal duration. Frequently the recurrence took place after as long a period of apyrexia as 15 days. In general, the course of the disease was favorable, that is, there were no deaths in uncomplicated cases. A 3 dose course of mapharsen increased the number of patients who suffered a single relapse of typhus. As a rule, penicillin produced a fall in temperature in the course of the first 24 hours; however a 4 day course of this drug did not prevent recurrence. Nevertheless the recurrent attack occurred later (after 14 or 15 days) as a rule and exhibited a milder course (1 or 2 days). The antireticular cytotoxic serum of Bogomilits did not produce remission of the attack when given alone, and, in the author's opinion, did not modify the duration of the individual attack nor prevent recurrence.

JOHN W. BRENNAN, M.D.

Tsilba, M. D., and Trushinskaya, M. M.: Peculiarities of the Disease Course in Abdominal Typhus in Children at Kiev from 1944 to 1945. *Pediatrics, Akusherstvo i Ginekologiya*, 1946, No. 2, p. 12.

Tsilba and Trushinskaya note that in the material of the Osmatdeta Institute for Infectious Diseases for the years 1944 and 1945 the cases of abdominal typhus in children ran a rather severe course in the majority of instances. In 74.6 per cent of the patients the course of the disease was severe or moderately severe. Especial attention is directed to the long period of complete morbidity and to the relapses and manifestations of the cardiovascular system. In the

neuropsychiatric sphere also there were pronounced manifestations. In many instances the early exhaustion of the nervous system was notable and there were pronounced manifestations of asthenia and psychic disturbances in the sense of a negativism. Encephalitic manifestations were both frequent and early.

The Widal reaction was positive in 54 per cent of the children with an outspoken clinical picture of typhus abdominalis appearing however more frequently in the later course of the condition, or even during convalescence. In two or three periods during the height of the clinical picture of typhus abdominalis, the characteristic macroscopic changes in the small intestines were found. However, in the great majority of children, microscopic examination failed to uncover the characteristic local hyperplasia of the reticular cells of the lymphoid tissues in Peyer's patches and in the regional lymph glands. Every picture of the changes in the lymphatic tissues in these young patients was characterized by the complete absence of germinal centers in the follicles of the lymph glands and by the poorly developed hyperplasia of the reticular stroma. In the authors' opinion this indicates a lowering of the reactive power of the organism of the child.

DUCTLESS GLANDS

Dougherty T. F., and Whitte, A.: Pituitary Adrenal Cortical Control of Lymphocyte Structure and Function as Revealed by Experimental X Radiation. *Endocrinology*, 1946, 39, 370.

A single injection of either pituitary adrenotropic hormone or adrenal cortical preparations have produced changes in lymphoid tissue similar to those seen following roentgen radiation. This suggested to the authors that pituitary-adrenal cortical secretion might be a normal physiological mechanism concerned with certain of the physiological actions of x rays. Recent studies, however, have demonstrated that whereas small doses of x-rays produced unmistakable alterations in lymphoid tissue structure and function of normal mice, large degrees of radiation would produce similar effects even in the absence of the animal's adrenals. These observations suggested further study with radiation.

Mice of both sexes, some of which were adrenalectomized, and male rats, some of which were either hypophysectomized or adrenalectomized, were used. Radiation was generalized over the entire body. Determinations were then made of the total white count, differential count, whole blood specific gravity, total serum protein, and their components as separated by electrophoresis and the anamnestic response to x rays of those animals immunized to sheep erythrocytes. A careful histological examination was also performed at autopsy particularly on all lymphoid structures.

X-irradiation of normal animals produces an increased secretion of pituitary adrenotropic hormone

as evidenced by a depletion of sudanophilic material of the adrenal cortex and a marked decrease in the total cholesterol content of the adrenals.

Irradiation of normal mice with 10 or 200 roentgens, and normal rats with 200 roentgens, produces a decrease in the absolute number of circulating lymphocytes. On the other hand, the adrenalectomized mice, given 10 roentgens, do not show a significant lymphopenia. Two hundred roentgens produce a profound leucocytosis with absolute lymphopenia in adrenalectomized mice or rats and in hypophysectomized rats. This effect could not be ascribed to hemodilution since the specific gravity of the blood was increased slightly. Handling of the mice prior to irradiation was found not to lower the lymphocyte count, as had been suggested by certain other investigators.

Irradiation of normal mice with 10 or 200 roentgens, or adrenalectomized mice with 200 roentgens revealed histologically a degeneration of lymphocytes with an initial development of macrophages, edema of the lymph nodes, and swelling of the reticuloendothelial cells. The disappearance of the lymphocytes resulted in a decreased size of these organs. These changes were similar to those observed in a previous study following the injection of adrenotropic or adrenal cortical hormones. Adrenalectomized mice exposed to 10 roentgens showed only very slight changes in lymphocyte structure and a shorter period of time for the maximal effect of lymphocyte dissolution. The most significant histological difference between the normal and adrenalectomized mice given 200 roentgens was the extreme rapid reconstitution of lymphoid tissue which occurred in the operated animals.

Irradiation produced in all instances a large increase in gamma globulin and a slight increase in the beta fraction. Alpha globulin of adrenalectomized mice, but not of normal mice, also increased following 200 roentgen exposure. The authors reason that the release of globulin to the circulation results from the normal dissolution of lymphocytes in lymphoid structures and is under pituitary-adrenal control unless large doses of radiation are used.

The anamnestic response was not marked in adrenalectomized mice given 10 roentgens in contrast to the response in the unoperated animals, or to large doses. This suggests that 10 roentgens influenced lymphoid tissue function by augmenting pituitary-adrenal cortical secretion.

Previous investigation has shown that one of the regulators of the rate of delivery of lymphocytes to the circulation is pituitary-adrenal cortical secretion. Lymphopenia following the administration of adrenal cortical steroids is a reflection of lymphocyte dissolution in lymphoid organs. Conversely the lymphocytosis of adrenalectomized animals is probably due to the absence of the hormonal mechanism normally controlling lymphocyte dissolution.

The authors suggest that x rays have both a direct and an indirect effect on the lymphocytes, the latter effect being mediated by the increased pituitary-adrenal cortical activity.

Housay, B. A., Foglia, V. G., and Martínez, C.: The Influence of the Thyroid on Alloxan and Pancreatic Diabetes in the Rat. *Endocrinology* 1946 39 351

This study concerns itself with the effect of the thyroid deficiency and thyroid excess on the diabetes produced in the rat by the administration of alloxan, or by the extirpation of 95 per cent of the pancreas. Hypothyroidism was produced by thyroidectomy or by treatment with thiouracil whereas hyperthyroidism was obtained by the administration of powdered thyroid. Alloxan was given either intravenously or intraperitoneally.

Thyroidectomized animals showed a greater resistance to the diabetogenic and toxic actions of alloxan than did normal animals. Resistance to alloxan was below normal 20 days after daily thyroid treatment, and above normal 60 days after daily treatment. Thiouracil treatment produced an even greater resistance to alloxan than did thyroidectomy. Thyroidectomy when performed simultaneously with pancreatectomy prevented the appearance of diabetes but had no effect on incipient or manifest diabetes. Thiouracil treatment prevented the appearance of diabetes after pancreatectomy in a large percentage of animals. Thyroid treatment in pancreatectomized rats caused an earlier appearance of diabetes during the first 15 days later, however this diabetic state gradually disappeared, not to reappear in spite of continuous treatment. Diabetes appeared in all contrasted rats and persisted. Incipient diabetes in pancreatectomized rats completely disappeared with thyroid treatment.

The authors postulate that thiouracil may increase the resistance to alloxan by virtue of the presence of sulfur or the sulphydryl group ($-SH$) in the thiouracil molecule. These experiments indicate that hypothyroidism exerts a certain degree of protection on the B cells which the authors suggest may be the result of (1) a relative functional rest of the islets since the lowered metabolism and rate of growth requires less insulin (2) a modification of the anatomical or chemical constituents of the islets, making them more resistant to diabetogenic factors and (3) increase in the production of insulin brought about by hypothyroidism.

Histological study seems to indicate that thyroid administration in rats, in continuous form would lead to an improvement or to the disappearance of diabetes due to a new formation of islets or to the enlargement of the existing ones in the portion of the pancreas which remains after operation. This is in contrast to the results obtained in the dog.

SURGICAL PATHOLOGY AND DIAGNOSIS

Bing, J., Neeser, J. Rasch, G., and Røsjel, K.: Serum Proteins in Normal People. *Acta med scand.*, 1946, 126 351

Although numerous investigations have been made concerning serum proteins and their fractional values

INTERNATIONAL ABSTRACTS OF SURGERY

in disease states the authors observed that there was a paucity of material regarding the protein content of normal serum. In reviewing the literature they noted a constant difference according to the method of protein analysis used. Of the two chief determinations, that of Henriques and Klausen is considered more exact when compared to the test of Howe.

The total serum protein albumin, and globulin were measured in 87 clinically normal people (38 males and 49 females) by the method of Henriques and Klausen. A careful statistical analysis of the results was made with attention to the variation according to sex and age. Although small differences were found for these factors they were so small that for practical purposes they can be ignored. The following values were obtained:

Total protein	5.6-8.2
Albumin	3.5-5.5
Globulin	1.6-3.2

C. FREDERICK KITTLE, M.D.

EXPERIMENTAL SURGERY

Blaine, G.: Experimental Observations on Absorbable Alginate Products in Surgery. *Ann. Surg.* 1947 125 102.

The author briefly describes important advances made in the prevention of adhesion formation in the course of tissue repair: the arrest of capillary hemorrhage and the closed treatment of burns through the development of new materials. He states that there are disadvantages to some of the materials previously used. He also states the qualifications of any new material to be used—absorbability at a readily controlled rate, the tissue reaction must compare

favorably with that of protein fibers and oxycellulose, the material must be easier and cheaper to produce, it must be compatible with penicillin and other antibacterial substances. It must allow sterilization by routine methods, its physical properties must allow modification of plasticity and it should be able to "carry" substances and ensure their controlled, delayed absorption in the organism. Such a material, he believes is found in the extract of brown seaweeds—alginate acid—the formula of which resembles that of cellulose. Many salts can be prepared from this acid. The sodium salt—sodium alginate (NaAlg)—undergoes instantaneous coagulation when acted upon by calcium. This reaction is the basis of preparing clot, film, filament (from which gauze can be woven) or foam. A certain limited range of rigid plastic objects can also be prepared.

The author describes the physical properties of the most useful salt—calcium alginate (alginate gel, film, gauze and foam)—its ready sterilization, its biochemical properties, and its physiological properties in animal tissues.

From the experiments on alginate products he concludes that this substance, used as clot, film or gauze is absorbed in animal tissues. Tissue reaction is minimal and the rate of absorption can be varied by the use of various strengths of sodium alginate or calcium chloride. The absorption rate varies with the physical form and bulk of the product—alginate cloth or gauze is slowest, the alginate film is quickest. Alginate products are readily autoclaved and have no inhibitory effects on penicillin. In view of these findings, the author believes "alginate products possess properties making them attractive for surgical use."

NUMBER 2

PULMONARY RESECTION FOR SOLITARY METASTATIC SARCOMAS AND CARCINOMAS

JOHN ALEXANDER M.D., F.A.C.S. and CAMERON HAIGHT M.D. F.A.C.S. Ann Arbor Michigan

THE appearance of a presumed solitary metastatic lesion in a lung months or years after the apparent complete removal of a primary extra pulmonary sarcoma or carcinoma is far from rare. If untreated surgically these patients almost invariably¹ die, usually from the invasive infectious or pressure effects of enlargement of the original metastatic lesion and from other metastases. A search of the literature reveals only 5² case histories (4 additional cases were merely mentioned by Churchill) in which both the primary and the metastatic pulmonary lesions have been removed. The first record is that of Barney and Churchill their patient being alive and well 12 years after removal of the metastatic lesion. The present report includes 19 additional case histories from various clinics which have not been published previously. Of the 24 patients 11 have had recurrence of their neoplasms 1 died as a direct result of operation and 12 are apparently free from recurrence. Among the latter however are 4 whose pulmonary resection operations were performed less than a year ago in 8 the operations were performed more than a year ago namely 12 7 6 5 4 3 1 1/4 and 1 years ago respectively.

An operation performed to remove a metastatic malignant neoplasm that is assumed to

be a solitary one (because no other can be found at the time) is obviously a gamble. As there is some chance of success and as failure to remove the lesion surgically will result in the death of the patient the operation needs no other justification.

The appearance of an x ray shadow of a tumor in a lung at the time of or months or even years after the removal of a malignant lesion from some other part of the body is *prima facie* evidence that the pulmonary tumor is a metastatic one. The chance of this being so is especially great if the tumor has sharply defined margins and if it is round. Nevertheless the pulmonary tumor may be primary and either malignant or benign. In many of the collected cases and in the University of Michigan Hospital patients H.A.B. and V.A.B. the surgeons could not determine before operation whether the pulmonary lesion was primary or metastatic and in several instances mistakenly believed them to be primary.

The presence of a bronchoscopically visible neoplasm is not proof that the lesion is primary in the lung since enlarging metastatic neoplasms not infrequently penetrate a bronchial wall or the metastasis may have first lodged in a bronchial wall. The histopathology of a bronchoscopic biopsy specimen usually indicates whether the lesion is metastatic to the lung or primary there. The presence or absence of pulmonary symptoms is of little or

From the Department of Surgery, University of Michigan.
¹Spontaneous disappearance of metastases has been reported.
²See footnote, No. 1.

no value in the differentiation between primary and metastatic pulmonary lesions since both may be symptomless when small or not involving a large bronchus, and both may produce symptoms when large or involving a large bronchus.

The most important criteria for the surgical removal of a presumed solitary pulmonary metastatic lesion are

- 1 A thorough physical and x ray examination shall have discovered no other metastasis. Such an examination should include careful palpation for enlargement of lymph nodes and liver and for tumors in the skin, bones, and all palpable organs. The chest x ray examination should include stereoscopic posteroanterior projection films and lateral or oblique projections as well as fluoroscopy in all standard projections. X ray films of the skull and all the long bones may be worth making.

- 2 Reasonable assurance should be had that the primary neoplasm has been completely removed. This is given if the primary neoplasm was removed 3 or more years before the contemplated pulmonary operation without the signs or symptoms of recurrence. In doubtful cases (e.g. see below Case Reports, University of Michigan Hospital, patients L.H.W. and A.B.) an exploratory operation and removal of a biopsy specimen may be advisable.

- 3 The patient must be in sufficiently good general condition for the contemplated pulmonary operation and with regard to pulmonary function able to spare a lung a lobe or a part of a lobe the extent of the resection depending upon the extent and location of the neoplasm.

The length of time that has passed between the complete removal of the primary neoplasm and the appearance of the presumed solitary metastatic lesion in a lung is important with regard to the validity of an assumption that the single demonstrable metastasis is actually the only one. If only one metastatic lesion (especially if it is a large one) can be found several years after the primary lesion has been removed there is probably a better chance that no other metastases exist than if the metastatic lesion were found shortly before or after removal of the primary lesion because in the latter instance relatively little

time has passed for the development of other metastases. This argument however is not wholly sound and not always applicable since the late appearance of a single small metastasis strongly suggests that it has been dormant or of a low grade of malignancy and therefore, that if other metastases are present they too may be small and not yet clinically demonstrable because of the absence of symptoms and physical and x ray signs. The lung owing to its radiotranslucency is a particularly favorable organ for the very early detection of a metastasis, perhaps before metastases in other organs can be found. It should be noted however that the discovery of a single pulmonary metastasis soon after or even before, the removal of the primary neoplasm does not necessarily indicate that other metastases will appear later. With due allowance for the exceptions mentioned, however the late appearance of a single metastasis offers a better chance that other metastases are not present than if the single metastasis appeared early.

When one or more metastases appear subsequent to the removal of a presumed solitary pulmonary metastasis, they may have arisen from the primary neoplasm before it was removed from some other metastasis that has not been detected or if the primary neoplasm had not been completely removed they may have come from it after the pulmonary resection operation. When one or more metastases appear within a few weeks or months after the removal of the original pulmonary metastasis, especially in cases in which one or more years have intervened between the removal of the primary neoplasm and the first symptoms or signs of the first metastatic lesion it is likely that these are second generation metastases and had their source in the original metastatic lesion. Pathologists not rarely find that the neoplastic cells of the pulmonary tumor which has been removed had penetrated its capsule or had traversed a blood vessel wall such unfavorable events are probably most likely to occur in tumors that have grown to a large size or that are composed of cells of relatively great malignancy.

As trauma of the tumor at the time of operation might be the determining factor in the dissemination of neoplastic emboli unusual

gentleness should be used in the handling of the lung and preferably the pulmonary veins should be ligated as early in the operation as possible. Since the chance of dissemination of the neoplasm from the original metastasis probably increases with growth of the tumor it should be removed as soon as possible and the temptation avoided of postponing a decision about operation while waiting to learn if later examinations of the patient might reveal other metastases.

The number of known cases in which a primary neoplasm and its pulmonary metastatic lesion have been removed is too small to determine the truth regarding the theoretical considerations discussed in the last three paragraphs or to justify the drawing of other conclusions from Table I. The 2 patients in whom the longest period elapsed between the removal of the primary neoplasm and the first symptom or sign of a pulmonary metastasis, namely 10 and 13 years respectively, had recurrences following resection of the original pulmonary metastasis.

Among the 24 cases there were 16 carcinomas and 8 sarcomas. Six of the 8 sarcomas but only 6 of the 15 carcinomas (excluding a carcinoma patient who died as a result of operation) are apparently free of recurrence. One of the sarcomas and 2 of the carcinomas, however, were operated upon less than 4 months ago and another sarcoma patient only 9 months ago. Four out of 6 renal cell carcinoma patients (including 1 operated upon a month ago) are free of recurrence. Only 2 other carcinoma patients are free of recurrence, 1 for 3 years and the other for 3½ months after pulmonary resection.

Only 1 of the 24 patients died as a direct result of operation. Safe operation however is of only incidental importance with regard to the subject of this article: freedom from recurrence 1 year, 3 years and especially 5 years after the pulmonary resection operation is, of course of major importance. 4 patients (see Table I) in whom no recurrence appeared within 1 year after the pulmonary operations are included in this article only because all known patients in whom both the primary and metastatic lesions have been removed are included. No patient is included whose pulmo-

nary lesion was removed first in the mistaken belief that it was a primary neoplasm, if the true primary neoplasm was not later removed. Occasionally two metastatic lesions have been removed by a single lobectomy or pneumonectomy operation: there are only two records known to us in which a second metastatic pulmonary lesion was removed by a subsequent pulmonary resection operation (University of Michigan Hospital patient L. H. W. and a patient mentioned by Churchill for whom bilateral partial lobectomy operations were performed). In all 24 cases the histopathologic examination of the pulmonary lesions indicated that these lesions were metastatic rather than primary in the lung.

The following reports include all cases of pulmonary resection for metastatic neoplasms (before or after removal of the primary neoplasm) we have been able to collect from publications (5 cases)² by casual inquiry among surgeons but not by systematic questionnaires (13 cases) and from the University of Michigan Hospital (6 cases), with the exception of 4 cases briefly mentioned in a table presented by Churchill in a 1940 article: 1 of Churchill's patients had a bilateral partial lobectomy, 2 had total lobectomy and 1 had total pneumonectomy. The only other information given about these patients is that there were no hospital deaths. A fifth patient listed in Table I is the one appearing below under Barney and Churchill. Almost certainly there are a considerable number of unpublished cases of which we have not heard: Dr Alfred Blalock, Dr Duane Carr, Dr O. T. Clagett, Dr F. S. Dolley, Dr Stuart W. Harrington, Dr Paul C. Samson and Dr Richard H. Sweet have generously sent us the unpublished histories of their patients with permission to use them in this article.

CASE REPORTS⁴

Well 12 years after partial lobectomy which was 15 months after nephrectomy for carcinoma

Since this article was prepared we have seen an article by Manderville (see References) in which 4 cases are reported in which both the primary and solitary metastatic pulmonary lesions were removed. One patient died during pneumonectomy and died from secondary metastases within a year after pneumonectomy. The prognosis in the fourth patient is grave because a large group of cancerous lymph nodes was found in the pulmonary hilum at the time of the recent pneumonectomy.

⁴The cases are arranged in chronological order with regard to the dates of their pulmonary resection operations.

TABLE I.—SIGNIFICANT DATA ABOUT THE 24 KNOWN PATIENTS WHO HAVE HAD PULMONARY RESECTION FOR METASTATIC NEOPLASMS

Patients of	Kind of neoplasm and site of the primary lesion	First symptom or sign of metastasis after removal of primary	Pulmonary resection after removal of primary	No sign or symptom of recurrence since pulmonary resection	First symptom or sign of recurrence after pulmonary resection	Death after pulmonary resection
		Years Months	Years Months	Years Months	Years Months	Years Months

The patients are listed chronologically according to the dates of pulmonary resection.

Only the 3 cases of Burns and Churchill; Brems and Lindskog; Ekins; and Timney and McDonald have been published before.

The patient's first lobectomy was followed by the appearance of second metastases for which another lobectomy was performed. The two lines of metastases were in the same area.

Multiple operations were performed for recurring carcinomas of the bladder and ureters during a period of 8 years and months. As the particular point from which the pulmonary metastases arose is not known, the metastases might have occurred at any time during this period.

doubled in size. On July 18, 1933, Dr. Churchill resected two-fifths (the lingular portion) of the left upper lobe including the tumor which measured 6 by 4 by 5 centimeters. There were no pleural adhesions although in one place the tumor extended to the visceral pleura. No pleural or lymphatic metastasis was seen. Microscopically the tumor consisted of renal adenocarcinoma cells that were much larger and more atypical than those in the renal tumor.

The patient was last seen 12 years after the removal of the pulmonary metastasis when she was 67 years of age. She was in perfect health and there was no demonstrable clinical or x-ray evidence of any other metastasis.

This is the earliest case of which we can find a record in which a metastatic lesion in the lung was successfully removed either before or after the removal of the primary malignant lesion.

Death 3 days after removal of left lower lobe and partial removal of left upper lobe which was 9 years and 4 months after resection of the jaw for carcinoma.

Dr. Frank S. Dolley's patient, 54 years of age, had an extensive resection of the mandible for carcinoma in 1928. A nonproductive cough developed in January 1937. Later chest x-ray films showed a circular shadow extending from the left border of the heart and an indefinite density at the left first costal level. On April 30, 1937, Dr. Dolley removed the lower lobe which contained a subpleural tumor 4.5 centimeters in diameter and also removed a wedge-shaped portion of the upper lobe which contained two subpleural nodules, the larger being 2 centimeters in diameter. The microscopic diagnosis was metastatic adamantinoma, probably derived from epidermal

Fig. 1. Patient L. H. W. Section from the Cleveland Clinic. Spindle cell sarcoma of neurofibromatous origin (ulnar nerve). Highly cellular tendency to form whorls, occasional division figures. Infiltration of voluntary muscle. A large nerve trunk is present within the neoplasm.

epithelial structures. The patient developed an extensive bronchial pneumonia and died 3 days after operation. Permission for a postmortem examination could not be obtained.

Well 6 years after the second of bilateral lobectomies which were performed 13 and 26 months, respectively after removal of a neurogenic sarcoma of the forearm.

L. H. W., No. 446282, a 22-year-old woman, a schoolteacher, was first admitted to the University of Michigan Hospital on July 7, 1939. In September 1937, a marble-sized nodule was noticed on the ulnar aspect of the left forearm a short distance below the elbow 2 weeks following a fall on this arm. The nodule was massaged for 9 weeks by a physiotherapist, during which time it increased in size, became tender, and

Fig. 2. Patient L. H. W. Roentgenograms of July 7, 1939. Round shadow in right lower lobe 1 year after sarcoma was removed from forearm. In a, left, the lesion is seen at the anterior end of the fourth rib and in b, overlying the spine (arrows).

Fig. 3 Patient L. H. W. Metastatic lesion in right lower lobe of lung of same type and degree of cellularity as lesion shown in Figure 1. Atelectatic lung surrounds the neoplasm.

numbness developed in the fourth and fifth fingers. In January 1938 an orange-sized tumor was excised but in March 1938 a still larger tumor appeared causing pain in the arm and hand. Sarcoma was diagnosed from a slide and x-ray therapy was given but without favorable effect.

In May 1938, the patient went to The Johns Hopkins Hospital where Dr. Dean Lewis advised amputation and Dr. Walter Dandy advised wide excision. The next month she consulted Dr. Alexander T. Bunts of the Cleveland Clinic. She was then having intractable pain in the arm and hand. Chest x-ray films showed no lesion. On June 7 1938 Dr. Bunts widely excised the tumor including the ulnar and median nerves and muscle masses. Microscopically

the tumor was a spindle cell neurogenic sarcoma (Fig. 1).

A year later the patient returned to Dr. Bunt because of pain in the hand and forearm. She had gained 16 pounds in weight during the preceding year. Although there was no palpable evidence of local recurrence Dr. Bunt reopened the incision on June 23 1939, finding only a benign neuroma in the stump of the ulnar nerve. He injected the proximal end of both the ulnar and median nerves with alcohol. Check up chest x-ray films at this time showed a 2 centimeter circular nodule in the right lower lobe. Dr. Bunt referred the patient to us for consideration of lobectomy.

We first saw the patient on July 7 1939. She had no cough, hemoptysis, dyspnea or pleural pain although she spoke of a mild aching in the right chest since learning of a lesion there a few days before. New x-ray films (Fig. 2) showed no change in the pulmonary lesion which on the basis of probability was considered to be a metastasis that had arisen from the forearm a year or longer previously rather than tuberculosis, a benign neoplasm, or a primary bronchogenic carcinoma.

The patient was obese weighing 145 pounds. Except for the defect in the upper left forearm and the atrophy of the muscles supplied by the ulnar and median nerves, a general physical and laboratory examination revealed no abnormality having any bearing on the present illness.

As only a single metastasis could be found 13 months after the primary neoplasm had been completely removed (as demonstrated by the exploratory operation on the forearm a year later) we agreed with Dr. Bunt that refusal to remove the metastatic lesion would be unjustifiable. On July 8 1939, therefore John Alexander removed the lower lobe of the

Fig. 4. Patient L. H. W. Roentgenograms of February 4 1940, 20 months after removal of sarcoma from forearm and 8 months after removal of right lower pulmonary lobe. Sharply margined shadow (arrow) appears to left of and behind, uppermost sternum. Roentgenogram to left shows elevated right diaphragm and rib defects resulting from lobectomy and empyema.

Fig. 5 Patient L. H. W. X ray film of June 17 1940. Great increase in size of left-sided lesion in 4 months (compare with Fig. 4)

Fig. 6 Patient L. H. W. Right anterior oblique roentgenogram of July 25 1940. Diagnostic pneumothorax shows that the left-sided tumor is in the lung not in the mediastinum

right lung. There were no pleural adhesions or fluid. The nodule was palpable deep in the lower lobe at the junction between its upper and middle thirds; there were no palpably enlarged hilar or mediastinal lymph nodes. Dr. R. C. Wanstrom of the Department of Pathology reported that the nodule measuring 3.5 by 2 by 2 centimeters was firm and well encapsulated. It was a spindle-cell neurogenic sarcoma (Fig. 3) of the same type and degree of cellularity as that removed from the forearm.

This 1939 lobectomy, which was among the last in this clinic performed by the tourniquet technique, was complicated by a shallow basal empyema with an intermittently open bronchopleural fistula. This condition was unusually troublesome because of pocketing in the broad shallow empyema space and was accompanied from time to time by fever and attacks of coughing and expectoration from the bronchial fistula. Several minor operations in the back and axilla were carried out before the empyema became obliterated and sputum ceased in May 1942.

Check up chest x ray films on February 14 1943 (Fig. 4) showed a homogeneous opacity with a well defined lateral border projecting from the left lateral border of the sternum above the aortic arch. In the lateral projection the mass lay immediately posterior to the plane of the sternum. This lesion had not been visible in the December 1939 roentgenograms. The patient was advised to have x ray therapy at home in Pittsburgh which she did not have. She returned on June 17 1940 when the lesion had increased more than twice in size (Fig. 5) since February. No other neoplastic lesion was visible.

The patient had gained 25 pounds during the preceding 6 months. A thorough physical examination revealed no other metastasis than that in the left lung and there was no sign of recurrence of the primary lesion in the forearm. As the absence of pleural

adhesions and the use of a tourniquet had permitted removal of the right lower lobe with almost no manipulation of the sarcoma deep within the lobe, the chance of this small lesion's having been the source of the metastasis to the left upper lobe seemed small. More likely was the chance that the metastases to both lungs had their source in the primary sarcoma before it had been completely removed 2 years previously. If this hypothesis were true only two metastatic lesions had become demonstrable in 2 years and there was at least a possibility that no others would appear. Small though this chance was, removal of the left upper lobe was recommended provided that a preliminary pneumothorax showed that the lesion was in the lung (which was found to be the

Fig. 7 Patient L. H. W. Metastatic spindle-cell sarcoma of left upper pulmonary lobe. More cellular and less well differentiated than the primary neoplasm or right pulmonary metastasis (compare with Figs. 2 and 3). Numerous cell division figures and hyperchromatic nuclei. In some areas the cells are losing their spindle form and are becoming large and round or oval. Extensive hemorrhage and necrosis.

Fig. 8. Patient L. H. W. on July 30, 1945

case (Fig. 6)) and not in the mediastinum. As the patient had been told elsewhere the nature of her trouble the situation with regard to operation was explained to her. She promptly chose operation small though she knew the chance of cure to be

The patient was readmitted to the hospital on July 24, 1940. The pneumothorax referred to in the last paragraph was induced and on July 26, 1940, John Alexander removed the left upper lobe which except for its lingular and inferior axillary segments, was almost entirely replaced by necrotic neoplasm. The only pleural adhesions were attached to the mediastinum above the pulmonary hilum and to the mesal first intercostal space and second costal cartilage. Many of these adhesions were found to be very vascular when divided. Division of the lower mediastinal adhesions, which apparently walled off an impending perforation of the cortex of the lung caused some of the semifluid necrotic contents of the neoplasm to spill into the pleural cavity which was thoroughly lavaged after the lobe had been removed. Those portions of the mediastinal and anterior parietal pleura that appeared as if they might contain sarcoma tissue were excised into grossly normal tissue and the mesal portion of the first internal intercostal muscle and what appeared to be the atrophic left lobe of the thymus gland were also removed. Microscopic examination of these tissues by Dr. R. C. Wamstrom showed no evidence of neoplasm. In the pleura were fibroblastic proliferation and organizing hemorrhage and in the thymus highly necrotic adipose tissue, occasional lymphocytic infiltration around vessels, and localized fibroblastic proliferation; in the intercostal muscle specimen were a group of cells suggesting a lymph node that had lost its follicular architecture. The pulmonary lobe and its necrotic hemorrhagic contents showed a spindle cell sarcoma that was more cellular and less well differentiated than the primary and right lower lobe neoplasms (Fig. 7).

During the 4 years following this operation the patient did very well except that the fear of recurrence caused an anxiety psychoneurosis that was manifested by such occasionally occurring subjective symptoms as aching in the throat, oppression at the suprasternal notch, blurring of vision and pain behind the eyes, a sensation of tightness in the throat and upper abdomen, an urge to gasp, undue dyspnea and a sensation of pressure around the forehead. Thorough physical examinations failed to reveal organic lesions as responsible for the symptoms. Knowledge of these findings and reassurance usually resulted in disappearance of the symptoms in a short time.

The last check up examination was made on October 17, 1946, which was 6 years after the second lobectomy, 7 years after the first lobectomy and 8 years after the removal of the primary sarcoma. There was no evidence of recurrence. The patient was in excellent health and during the preceding 2 years, she had worried little about recurrence and had been virtually free of the symptoms of anxiety psychoneurosis.

11 7 years after pneumonectomy which was 4 years after removal of breast sarcoma

Dr. Richard H. Sweet's patient No. 2, a woman, had a radical mastectomy performed by Dr. Daniel Fiske Jones and Dr. Sweet on January 1, 1935, for an immense sarcoma. The patient was well for 4 years and then developed a troublesome cough. X-ray examination showed a large round shadow in the right lower lung. No other evidence of primary or secondary neoplasm could be found. On November 3, 1939, Dr. Sweet removed the right lung. A tumor of the lower lobe had invaded by direct extension the adjacent surfaces of the middle and lower lobes. Microscopically the tumor was seen to have been metastatic from the breast sarcoma. The patient has been carefully followed to October 25, 1946 (7 years

after pneumonectomy) and has had no sign of recurrence or other metastases.

Recurrence 3 months after pneumonectomy which was 22 months after removal of a sigmoid carcinoma

Dr Forrester Raine's patient was a woman of 50 years of age who had had a carcinoma of the sigmoid removed in January 1939. In October 1939, coughing began and increased until she was admitted to the Milwaukee County Hospital on August 27 1940. She then had a severe hemoptysis fever night sweats and had lost 40 pounds in weight between October 1939, and September 1940.

X ray examination of the chest showed a shadow in the region of the right middle and lower lobes but no nodules elsewhere. There was no sign of recurrence of the sigmoid carcinoma. The liver was not enlarged and there was no palpable enlargement of lymph nodes. Bronchoscopy showed a large papillary mass in the right main bronchus just below the upper lobe bronchus; a biopsy specimen revealed adenocarcinoma typical of carcinoma of the colon.

A pneumonectomy was performed on October 14 1940. In addition to the principal tumor mass a separate nodule was found near the base of the lower lobe. Early in January 1941 the patient developed gastric distress and "presumably had metastasis near the liver."

Eleven years after pneumonectomy which was 3 years after nephrectomy for carcinoma

Dr W. S. Tinney's and Dr J. R. McDonald's patient a woman 39 years of age had a right nephrectomy for a renal cell carcinoma in July 1938 after 9 months of hematuria. A neoplastic thrombus was found in the renal vein. The patient was well until July 1940 when she had chest pain nocturnal dyspnea cough and hemoptysis. Bronchoscopy showed a tumor in the left upper lobe bronchus; a biopsy of which revealed a renal cell carcinoma.

The left lung containing a 5.5 by 4 by 3.5 centimeter tumor mass surrounding the major vessels and bronchi was removed by Dr Stuart W. Harrington on August 20, 1941 (sic). The tumor consisted of a metastatic grade 1 papillary renal cell carcinoma; the peribronchial lymph nodes contained carcinoma cells. The patient was last seen on June 8 1946 and was heard from on July 10 1946; she was in excellent general condition weighing 183 pounds and had no complaints except slight hemoptysis and an occasional cough. A bronchoscopic examination on June 5 1945 showed that the stump of the left main bronchus was in good condition; some inflammatory reaction and a small amount of blood were found in the right lower lobe bronchus; bronchiectasis was considered but not proved.

Eleven years after lobectomy which was 21 months after removal of a sarcoma of the thigh

AB No 473 121 a surgeon 50 years of age was first seen at the University of Michigan Hospital by Dr Frederick A. Collier on December 30 1940.

Fig. 9. Patient L. H. W. Last check up x ray film of October 17 1946. No evidence of recurrence 6 years after removal of second pulmonary metastasis, 7 years after removal of first pulmonary metastasis and 8 years after removal of primary neurogenic sarcoma of forearm.

Three weeks previously the patient had noticed an increase in the size of his lower right thigh. An initial peculiar sensation was succeeded by a dull ache. He had no recollection of trauma of the thigh. His father had died of carcinoma of the rectosigmoid at the age of 93 years and his maternal grandmother had died of carcinoma of the uterus. Otherwise the family's and the patient's own medical histories are not relevant to the present illness.

In general appearance the patient seemed to be well. His weight of 150 pounds was his usual weight. The blood pressure was 123/76 the hemoglobin 100 per cent the white blood cells 10,300 the urine normal and the blood Kahn reaction negative. On the lateral aspect of the right thigh extending from 10 to 20 centimeters cephalad to the patellar level there was a mass measuring approximately 10 by 5 centimeters, moderately fixed in the muscle firm and not fluctuant, and not reddened or tender. X ray films of the femur lumbar spine pelvis and chest and the general physical examination revealed no evidence of significant abnormality.

The thigh tumor which appeared to arise in the epimysium of the vastus lateralis and which was not attached to the femur was removed with an adequate margin of surrounding tissue by Dr Collier on December 31 1940. The Department of Pathology reported (this and all the subsequent pathology reports about this patient were made by Dr C. V. Weller or Dr R. C. Wanstrom) that the specimen weighed 168 grams and measured 10 by 6 by 6 centimeters. Microscopically the tumor was a spindle cell fibrosarcoma with many bizarre hyperchromatic nuclei; the voluntary muscle was infiltrated (Fig. 10).

On July 22 1941 a nodule in the skin scar which was believed to be an implantation metastasis, was

Fig. 6. Patient A. B. Spindle-cell fibrosarcoma from lower thigh. Many bizarre hyperchromatic nuclei, areas of necrosis, infiltration into skeletal muscle.

excised. It showed adipose and connective tissue infiltrated with spindle-cell sarcoma having many hyperchromatic nuclei.

Without Dr. Collier's approval the patient was given x-ray therapy of the former tumor area at another hospital between July 30 and August 15, 1941.

Chest x-ray films of June 24, 1941, and lumbar spine and pelvis roentgenograms of August 4, 1941, showed no significant abnormalities. The chest roentgenograms of August 4, 1941, however, showed

a small, smoothly rounded shadow at the lower border of the anterior first right rib which had not been visible in any previous x-ray film. Four other chest roentgenograms taken between August 4 and Sep-

Fig. 7. Patient A. B. Metastatic spindle-cell sarcoma of right upper pulmonary lobe exactly like that of thigh (Fig. 6). The lesion appears to be growing slowly.

tember 22 showed no change in the size or shape of the lesion, and no other lesion could be seen. Although tuberculosis and other conditions were considered as possibilities in the differential diagnosis, metastatic sarcoma seemed most probable and the case was, therefore, managed on this assumption.

Fig. 8. Patient A. B. Roentgenograms of September 22, 1945, 28 months after sarcoma was removed from thigh. Circular metastatic lesion is indicated by arrows.

Fig. 13. Patient A. B. Photographs of July 13, 1945. At left, the lobectomy incision is faintly visible. At right area of excision of sarcoma of thigh and subsequent x ray dermatitis has been skin grafted. Small ulcers on femur are not malignant.

We first saw the patient on September 3, 1942. He was understandably very apprehensive and had doubled his cigarette smoking from one to two packs a day which was followed by an increase in his cigarette cough and yellowish white sputum. Otherwise he had no symptoms and no thoracic pain. Physical examination revealed no important abnormality and there was no evidence of metastasis except the single supposed one in the right lung. The cervical, axillary, and inguinal lymph nodes were not enlarged. The thigh incision was healed except for two small necrotic areas in stitch scars. The region was firm, indurated and not tender; there was considerable roentgen dermatitis.

As nearly 21 months had passed since the removal of the primary sarcoma (13 months since the nodule in the skin incision had been removed) and as there was no evidence of any metastasis except the single one in the right lung, its removal seemed almost mandatory, provided that no recurrence had taken place in the thigh. On September 5, therefore, Dr. Collier removed 3 large slices from the indurated region of the thigh that had contained the primary sarcoma and that had become greatly fibrosed following x-ray therapy. Microscopic examination of 27 sections of this material revealed no evidence of recurrence.

On September 23, 1942, John Alexander removed the upper lobe of the right lung. The small nodule was immediately beneath the visceral pleura in the anterior part of the lung 3 centimeters inferior to the apex. There were no overlying pleural adhesions. A few tiny anastomatic lymph nodes were present

Fig. 14. Patient A. B. X-ray film of October 16, 1946, 4 years after lobectomy and 5 years and 8 months after removal of thigh sarcoma. No evidence of recurrence. The costophrenic angles are obliterated—the right as a result of the lobectomy and the left as a result of an old pleuritis.

among the hilar structures. A 9 by 3 centimeter portion of the upper lobe was congenitally fused with the apical portion of the lower lobe, requiring sharp division.

Gross examination of the lobe and microscopic examination of 7 large blocks of tissue showed only a single neoplastic nodule. This measured 3 by 8 by 12 millimeters. It was a spindle cell sarcoma (Fig. 12) exactly like that found in the thigh. Its center was necrotic and it appeared to have been growing only slowly.

The patient had an uneventful convalescence and was discharged from the hospital on October 6, 1942.

In January, 1943, a wide excision was made by Dr. Collier of the roentgen dermatitis area of skin and its contained ulcers and of the underlying fibrosed tissues. Microscopically no neoplasm was found. In February, 1943, Dr. Henry Ramson covered the denuded area with a split thickness graft 95 per cent of which lived.

The patient was last examined on October 16, 1946, 4 years after the lobectomy and 5 years and 8 months after the sarcoma of the thigh had been removed. He has no symptom or physical or roentgenographic (Fig. 14) sign of recurrence of the sarcoma. Flexion of the right knee is limited to 10 degrees because of a catching of the quadriceps tendon. He operates for approximately 5 hours on each of 5 days a week.

Recurrence (subsequent death) 1 year after lobectomy which was 10 years after removal of a carcinoma of the ovary.

Fig. 6. Patient A. B. Spindle-cell fibrosarcoma from lower thigh. Many bizarre hyperchromatic nuclei, areas of necrosis. Infiltration into voluntary muscle.

excised. It showed adipose and connective tissue infiltrated with spindle-cell sarcoma having many hyperchromatic nuclei.

It was a spindle cell sarcoma (Fig. 12) exactly like that found in the thigh. Its center was necrotic and it appeared to have been growing only slowly.

The patient had an uneventful convalescence and was discharged from the hospital on October 9, 1942.

In January, 1943, a wide excision was made by Dr. Coller of the roentgen dermatitis area of skin and its contained ulcers and of the underlying fibrosed tissues. Microscopically, no neoplasm was found. In February, 1943, Dr. Henry Ramson covered the denuded area with a split thickness graft, 90 per cent of which lived.

The patient was last examined on October 16, 1946, 4 years after the lobectomy and 5 years and 8 months after the sarcoma of the thigh had been removed. He has no symptom or physical or roentgenographic (Fig. 14) sign of recurrence of the sarcoma. Flexion of the right knee is limited to 10 degrees because of a catching of the quadriceps tendon. He operates for approximately 5 hours on each of 5 days a week.

Recurrence (subsequent death) 1 year after lobectomy which was 10 years after removal of a carcinoma of the ovary

Dr Richard H. Sweet's patient No. 2 a woman, was found by x ray examination to have an irregular shadow in the right upper lung field which was diagnosed as bronchogenic carcinoma although a bronchoscopic examination showed no lesion. Dr Sweet removed the right upper lobe on January 26 1943. Microscopic examination of the tumor indicated that it was not primary in the lung. Further inquiry into the patient's history revealed that an oophorectomy had been performed for a cyst 10 years previously at another hospital. Microscopic comparison of the tumors of the ovary and lung showed that both were carcinomas of identical type. About 1 year after the lobectomy recurrence was found in the chest although not in the pelvis and the patient subsequently died.

Death 2 years after pneumonectomy which was 13 years after hysterectomy for carcinoma.

Dr P. S. Breszina and Dr G. E. Lindskog's patient was a woman of 65 years of age when she was admitted to the New Haven Hospital on April 5 1943, complaining of cough of 6 months duration and blood streaked sputum of 5 months duration. Thirteen years previously she had had at another hospital a subtotal hysterectomy and bilateral salpingo-oophorectomy carcinoma was diagnosed by gross inspection of the lesion but a microscopic examination was not made.

April, 1943 x ray films showed a 9 centimeter mass in the right lung at the hilar level. Bronchoscopy revealed puckering of the right main and upper lobe bronchi but a biopsy specimen did not show carcinoma. A pneumonectomy was performed on April 17 1943. There were no pleural adhesions and no enlargement or microscopic involvement of the mediastinal lymph nodes. The necrotic tumor which was in the upper lobe and had a very thin capsule was composed of columnar-cell glands. The pathological diagnosis was metastasis from adenocarcinoma of the uterus.

When the patient was last examined on September 29, 1943 5½ months after the pneumonectomy she was in good general condition and without evidence of recurrence in the pelvis, lung or elsewhere. The patient died at home or in another hospital with carcinoma in the liver on April 2 1945 2 years after the pneumonectomy.

Well 3 years after pneumonectomy which was 4½ years after resection of rectal carcinoma.

Dr Alfred Blalock's patient a man 54 years of age was admitted to The Johns Hopkins Hospital on September 10, 1943. In March 1939, a rectal carcinoma had been removed and in the following July the sigmoid was anastomosed to the remains of the rectum.

In October, 1942 the patient developed a cough and a cold which persisted for a month. Increasingly severe colds recurred for 7 months. During the following 3 months he had a persisting cough low-grade fever and loss of energy but no hemoptysis. Chest

roentgenograms made during this 3 month period were at first interpreted as showing only pulmonary infection of the right lower lung and later as an enlarging neoplasm.

Otherwise the past medical history and the family history are not relevant to the illness under consideration. On physical examination the right pulmonary base was dull to percussion and it descended fairly well during inspiration, breath sounds were normal. Examination of the abdomen, rectum, genitalia, and extremities revealed nothing of importance. On September 22 1943 Dr Blalock removed the right lung believing that the tumor mass was either a solitary metastasis from the rectal carcinoma or a primary bronchogenic carcinoma. Microscopically it proved to be an adenocarcinoma, presumably metastatic from the rectum.

When last seen in October 1946 3 years and 1 month after the pneumonectomy, there was no sign of recurrence. During the preceding 11 months the patient had had recurrent attacks of epididymitis, head and chest colds and one attack of pneumonia, from which he made a rapid recovery.

Death 10 months after pneumonectomy which was 4 years and 10 months after a thigh amputation for sarcoma.

Dr Duane Carr's patient a man of 26 years of age, had had a left thigh amputation for osteogenic sarcoma in January 1939. A routine chest roentgenogram in February 1943 showed a 3 inch round sharply defined mass of homogeneous density opposite the right pulmonary hilum. At this time there were no symptoms but in July 1943 a morning cough developed and a 3 ounce hemoptysis occurred and was followed by small hemoptyses or blood streaked sputum almost every day.

Dr Carr first saw the patient on November 3 1943. A thorough physical examination disclosed no evidence of any tumor except that in the right lung. Roentgenograms of all the long bones, the pelvis, spine and skull showed nothing suggestive of neoplasm. On November 9, 1943 Dr Carr removed the right lung. The tumor was found hard apparently encapsulated and had a diameter of 8.5 centimeters. The medial border of the tumor was engaged in the hilum. The pathological report stated that the tumor which was an anaplastic fibrosarcoma, contained areas of necrosis and appeared to have perforated the medial aspect of the capsule in several places.

The patient was doing part time office work in March 1944. Late April a small nodule appeared on his temple, enlarged and was removed by another surgeon. The patient developed a transverse myelitis and x-ray films of July 21 1944 showed destruction of the seventh and eighth thoracic vertebrae. The patient died about September 1944.

Death 5½ months after pneumonectomy which was from 15 months to 8½ years after various resections of urcinomatous papillomas of bladder and urethra.

Fig 15. Patient R. L. L. Roentgenograms of August 25, 1945 showing tumor in right lower lung posteriorly

Dr C. L. Deming's and Dr G. E. Lindskog's patient a man 54 years of age was first known to have bladder papillomas in 1931. In 1935 a biopsy showed probable malignancy and a later biopsy showed definite malignancy. Cauterization was carried out. Other papillomas were removed from the bladder and urethra during the next 2 or 3 years. Radium was used. The membranous and anterior urethra was excised on January 10, 1941 because of stricture and papillomas. Other papillomas were removed and in September, 1942, the end of the penis was amputated because of an infiltrating papilloma of the meatal mucosa.

Beginning in June, 1943, cough, chest oppression and pain developed. Roentgenograms showed a pulmonary tumor but no evidence of metastasis to bones. The bladder and posterior urethra showed no recurrence of papilloma. The right lung was removed on December 7, 1943. Microscopically the tumor of the upper lobe had a cellular arrangement similar to that of the tumors of the bladder and urethra. In February, 1944, there was evidence of metastasis to the right iliac crest and the patient died on May 22, 1944.

Death 2 years after pulmonary lobectomy which was 15 months after orchidectomy for a teratoma.

Dr Stuart W. Harrington's patient was a man who had had a left orchidectomy for a teratoma in another clinic in March, 1943. A solitary pulmonary metastasis was first noted by x ray in February, 1944. There were then no pulmonary symptoms. The tumor failed to respond to intensive x ray therapy and increased in size.

The patient was in very good general condition when seen by Dr. Harrington, who removed the lower lobe of the right lung on June 10, 1944. The

tumor was a fairly well delimited metastatic teratoma, 4 by 2.5 by 2.5 centimeters in size and contained a few areas of grade 2 adenocarcinoma.

The patient appeared well until 1½ years later when x ray examination showed a mediastinal mass which gradually increased in size in spite of x ray therapy. Death occurred 2 years after lobectomy.

Well 9 months after lobectomy which was 26 months after resection of a thoracic wall sarcoma.

Dr Richard H. Sweet's patient No. 3, a man in his middle fifties, had a fibrosarcoma excised from his thoracic wall on December 4, 1942. More than 2 years later a very small, lobulated shadow appeared by x ray in his left lower lobe, which was removed on January 31, 1945, on the assumption that the lesion was probably a single metastasis. Microscopically the pulmonary lesion was shown to be a fibrosarcoma. Nine months later the patient was apparently well. He failed to report for examination during the following year.

Well 15 months after lobectomy which was 3 weeks after nephrectomy for carcinoma.

Dr Richard H. Sweet's patient No. 4, a man, had had an abdominal nephrectomy for a renal cell carcinoma. Three weeks later in March, 1945, Dr. Sweet removed the left upper pulmonary lobe for a solitary metastasis. When last seen in June, 1946, 15 months after the lobectomy, the patient was apparently well.

Probable cerebral metastasis 6 weeks after lobectomy which was 2 months after nephrectomy for carcinoma subsequent death.

Dr Richard H. Sweet's patient No. 5, a man, had a right nephrectomy early in June, 1945, for a renal

Fig. 16 Patient H A B. X-ray film of January 5 1946, showing large tumor with clearly defined and lobulated margins.

cell carcinoma. A small rounded shadow was discovered in the left upper pulmonary lobe, which Dr. Sweet removed on July 30 1945. Approximately 6 weeks later the patient had a hemiplegia which his home physician assumed was due to a cerebral metastasis or possibly a cerebral embolus.

Well 23 months after double lobectomy which was 2 years and 5 months after amputation for a sarcoma of the thigh

R.L.L. No. 470,334, 29 year old man, a groundskeeper noticed a small tumor above his left knee 4 months following a kick by a horse in 1934. The tumor was removed and found to be a fibrosarcoma. In 1938, a recurrent tumor was excised and recurred again. When first seen at the University Hospital in October, 1941 it was fixed in the deep tissues above and mesial to the knee and measured 4 by 3 by 3 centimeters. This tumor was removed at another hospital.

The patient was readmitted on February 17 1943, 4 days after he noticed a 4 centimeter tumor mass fixed in the left popliteal space. This tumor which lay between the popliteal artery and the femur was removed on February 25 1943 by Dr. John Lawther. Microscopic examination was reported by Dr. C. V. Weller as showing a necrotic spindle-cell fibrosarcoma with many hyperchromatic nuclei and in some areas it was highly cellular—more cellular than it was in 1940. The neoplasm was found to extend beyond the area of excision. Apart from this finding the Tumor Conference had recommended before this operation was performed that amputation be car-

ried out if the sarcoma were found to have increased in cellularity. A high thigh amputation was performed on March 25 1943 by Dr. Lawther. Microscopically no neoplasm could be found from the examination of many sections.

The patient remained well and worked until April, 1945 except for traumatic fractures of his hand shortly before then. In April he developed an irritative cough with mucopurulent sputum. For a few days late in July these symptoms increased and a temperature of 104 degrees dropped rapidly with penicillin and sulfonamide therapy. On August 24, 1945 he was readmitted to the University Hospital. Physical examination indicated an extensive infiltration in the right lower posterior hemithorax. X-ray films showed a large intrathoracic mass with smoothly rounded superior and anterior borders, suggesting a metastatic lesion (Fig. 15). No other lesion could be seen in either lung. Chest x-ray films of October 29, 1940 and February 17 1943 had showed no abnormality. Films received from another hospital showed a right-sided lesion on April 30 1945.

Physical examination revealed no other metastases than the single one in the right lung. No pleural fluid was recovered by needle aspiration of the right lower chest. Bronchoscopy by Cameron Haight on August 27 1945 showed a tumor mass occluding the right intermediate bronchus but not involving the upper lobe bronchus. Microscopically a biopsy of this tumor revealed spindle-cell fibrosarcoma infiltrating beneath the respiratory epithelium (this and the subsequent pathology report were made by Dr. R. C. Wanstrom).

On September 4 1945, Cameron Haight removed the right lower and middle pulmonary lobes together with most of the intermediate bronchus into which a pedunculated portion of the tumor had extended but to the wall of which it was not attached. The tumor measuring 9 by 6.5 centimeters occupied the upper portion of the lower lobe. The lower and middle lobes were atelectatic. The entire pleural cavity was obliterated by adhesions. No enlarged lymph nodes were palpable in the hilum or mediastinum. Microscopically, the intermediate bronchus showed no neoplasm. The lung showed infiltration by spindle-cell sarcoma and the consequences of bronchial obstruction, i.e. bronchiectasis chronic purulent fibroid pneumoniae and organizing fibrinous pleuritis.

The patient was last seen as an out-patient on October 9, 1946 3 months after the double lobectomy and 3 1/2 years after the thigh amputation. He resumed his work as groundskeeper 5 weeks after the double lobectomy but did no heavy lifting for another 6 months. He has felt perfectly well, has gained 32 pounds and has had no cough, cold, or any illness. Chest x-ray films show no evidence of neoplasm.

Possible cerebral metastasis 8 months after lobectomy which was 4 years after excise of rectal carcinoma.

Dr. O. T. Claggett patient No. a man 50 years of age had an ulcerating grade 3 carcinoma of the mid and lower rectum removed in July 1941. In

Fig. 17 Patient I. L. M. Left, roentgenogram of March 18 1946 showing two tumors in right lung, the smaller one underlying the fifth costal cartilage. Right, x-ray film of June 27 1946 showing metastasis in left lung after right pneumonectomy.

November, 1945 he was found to have a tumor in the right chest which had not been present on roentgenologic examination 1 year previously. Bronchoscopy showed no bronchial lesion. A solitary metastasis in the lung was suspected. A right upper lobectomy was carried out by Dr. Clagett on November 29 1945. The lesion which was 4 by 3.5 by 2 centimeters in size, proved to be an adenocarcinoma grade 2. In July 1946 the patient was found to have the symptoms and signs of a possible cerebral metastasis.

Recurrence 9 months after partial lobectomy which was 2 years after nephrectomy for carcinoma

Dr. Richard H. Sweet's patient No. 6 had a nephrectomy for a renal cell carcinoma. Two years later his physician who had made frequent x-ray examinations because of the possibility of discovering an early solitary symptomless pulmonary metastasis found a small nodule in the right lower lobe. In December 1945 Dr. Sweet removed the small nodule together with a margin of adjacent pulmonary tissue by means of a segmental partial lobectomy. Nine months later a check up x-ray examination revealed numerous small round shadows throughout both lungs which were interpreted as multiple metastases, although the patient appeared to be reasonably well.

Death 5 months after pneumonectomy which was 6 years after resection of a rectal carcinoma

I.L.A.B. No. 386,405 49 years of age, a toolmaker was admitted to the University Hospital on January

14, 1946. Six years previously Dr. F. A. Collier had removed a rectal carcinoma by combined abdominal and perineal resection at another hospital. The patient was perfectly well until January 1944 when he developed a cough productive of 1 or 2 teaspoonsful of grayish sputum daily. During the year before admission he felt fatigued and 2 months before admission had a 15 cubic centimeter hemoptysis and developed a dull pain in his left shoulder extending to the elbow and the base of the neck. An occasional wheeze disappeared after expectoration. There had been no loss of weight.

The past medical and family histories were not significant. Physical examination including that of the lungs, revealed no abnormality of importance. Chest roentgenograms (Fig. 16) showed a large mass with clearly defined and lobulated margins in the left lower lung; no other lesion was seen in either lung and the hila were not enlarged. The thoracic cage and spine showed no abnormality.

The patient was bronchoscoped by Cameron Haight on January 14 1946. A lesion suggesting a primary bronchogenic carcinoma was obstructing the lingular bronchus; a biopsy specimen showed adenocarcinoma. On January 17 1946 Cameron Haight removed the left lung. The lesion approximately 8 centimeters in diameter occupied the lingular and axillary segments of the upper lobe and the anterior segment of the lower lobe. The lesion was firmly adherent to a 6 by 8 centimeter area of the pericardium but there was no gross evidence of pericardial invasion. The tumor in the lung contained large areas of necrosis. Dr. W. A. Stryker of the Depart-

Fig. 18. Patient V. A. B. X-ray film of October 3, 1946, showing triangular shadow and 3 small nodules in right lung.

ment of Pathology reported an adenocarcinoma metastatic suggesting metastasis from the rectal carcinoma. The cancerous infiltration extended into the adventitia of a number of blood vessels. One mediastinal lymph node contained carcinoma cells and two others did not.

The patient was discharged on February 1 but returned frequently as an out-patient, and for 3 weeks in April as an in-patient complaining of dyspnea and pain in both the right and left sides of the chest. Spine x-ray films showed no lesion. The mediastinum was displaced only slightly toward the left. On April 20, 1,000 cubic centimeters and on April 23, 1,300 cubic centimeters, of slightly cloudy fluid were aspirated from the right pleural cavity with great relief of dyspnea. No carcinoma cells could be found in either specimen. The dyspnea recurred on April 25 but no more fluid could be seen by fluoroscopy or recovered by needle. Although a metastatic lesion could be seen in the April x-ray films the occurrence of the right-sided pleural fluid dyspnea, and right-sided thoracic pain made the presence of metastasis reasonably certain. The patient died in June 1946. There was no autopsy.

Well 3 weeks after lobectomy which was 4 years after amputation for a sarcoma of the os calcis

Dr. O. T. Clagett's patient No. 2, a man 55 years of age, had an amputation for a grade 1 chondrosarcoma of the right os calcis in October 1941. He returned to the Mayo Clinic in January 1946, with a lesion in his right chest, which was suspected of being a metastasis. Dr. Clagett removed the right upper

pulmonary lobe on February 19, 1946. The lesion was found to be a grade 1 osteogenic sarcoma and measured 12 by 8 by 5 centimeters. The patient was discharged on March 12, 1946.

Recurrence 7 weeks after pneumonectomy which was 5 months after removal of a sarcoma of the leg

J. L. M. No. 386,608, a 49-year-old Philippino man, a student, was first admitted to the University Hospital on March 15, 1946. In March or April 1944, a corn grain sized movable nodule was removed from the tissues over the head of the left fibula. The tumor recurred and in October 1944, it was 3 centimeters in diameter and was removed. In July 1945, it recurred, grew rapidly and was partly removed. An aspiration biopsy was carried out in September showing sarcoma. In October 1945, the lesion was apparently completely excised. Neither fluoroscopy of the chest in November nor chest x-ray films at the Chicago Tumor Institute and at the University of Michigan Health Service in January 1946 revealed any abnormality. Roentgenograms of February 13, 1946, showed two small rounded nodules in the right mid and lower lung fields, the left lung and the hilum were clear. By March 18, the lesions had definitely increased in size.

At the time of his admission he said that for a few months he had had a dry cough, the occasional expectoration of mucus, increasing dyspnea and, recently, some bloody expectoration. Since April 1945, he had had malaria and measles. He had been severely malnourished during the Japanese occupation of his homeland. His weight on March 15 was 108 pounds, his best weight was 126 pounds.

The patient did not appear ill. His temperature was normal and his blood pressure 108/70. There were no abnormal physical signs from the lungs (Fig. 17). The cervical, axillary and inguinal lymph nodes were not enlarged. No mass or enlarged organ was palpable in the abdomen. There was no palpable or roentgenographic sign of recurrence of the leg tumor. There was no evidence of any metastasis except those in the right lung.

The right lung was removed on March 25, 1946, by Dr. George R. Minor. The upper and middle lobes were free of adhesions but the lower lobe was covered by avascular adhesions. Only small anastomotic lymph nodes were present in the hilum. The diameter of the upper lobe metastasis was 2.5 centimeters and that of the lower lobe 2 centimeters. The tumors were highly cellular spindle-cell sarcomas with osteoid matrix. There were marked pleomorphism and many division figures. Tumor thrombi or emboli were present in veins, and masses of neoplasm in bronchi. This report of Dr. W. A. Stryker of the Department of Pathology states that the primary neoplasm was probably osteogenic.

The patient was discharged on April 9. Check-up roentgenograms on May 17 showed for the first time a rounded lesion in the lower left lung, measuring 2 by 3.5 centimeters. On September 10 it measured 5 by 7 centimeters. The lesion had failed to respond

to x-ray therapy. 600 roentgens having been given to each of two fields on May 22 and 23. The patient was seen for the last time on September 25 when he appeared cachectic. He was dyspneic and had great pain in the region of the thyroid cartilage on swallowing or turning his head toward the left. Almost certainly he will soon die from progression of his metastases.

Well 3½ months after lobectomy which was 6 years after removal of carcinoma of colon

Dr Paul C. Samson's patient No. 1, a man now 69 years of age, a bank employee, had a right-sided colectomy for carcinoma in mid 1940. A chronic cough of 30 years' duration increased late in May 1946 and during the next week blood was expectorated. There was no loss of weight or chest pain. X-ray films showed a rounded mass 3 inches in diameter in the left lower pulmonary lobe. Bronchoscopic biopsy showed only inflammatory tissue. The mass increased in size during the period of a month. On July 12, 1946, the left lower lobe was removed. Lobectomy was chosen instead of pneumonectomy because (1) frozen sections of the hilar lymph nodes showed no malignant cells, (2) the tumor was in a peripheral location and (3) the patient was quite elderly. Several degenerated areas in the soft tumor contained mucoid material; the lining was composed of highly differentiated mucoid adenocarcinoma with papillary ingrowths, microscopically almost identical with colon carcinoma.

The last check-up examination was on November 1, 1946, when there were no symptoms or fluoroscopic evidence of recurrence.

Consolidating 1 month after pneumonectomy which was 5½ years after nephrectomy for carcinoma

V.A.B. No. 254,460, a man of 53 years of age, a machinist, had a left-sided nephrectomy by Dr. Reed Nesbit for a renal cell carcinoma on April 5, 1941, following 2 weeks of symptoms and a single episode of hematuria 2 years before. Roentgenograms in 1941 showed no sign of a pulmonary neoplasm. In 1944 he had symptoms suggesting the possibility of coronary disease but this diagnosis was not established by examinations.

In May 1946 the patient began to cough, had a fever of 102 degrees and pain in his right chest. Bronchial pneumonia of the right mid lung was diagnosed elsewhere. Improvement with penicillin was rapid and x-ray films during the next month showed a definite decrease in the area of pulmonary infiltration. Roentgenograms of July 16, 1946, showed a smoothly margined triangular area in the right upper lung (Fig. 18). A month later there was almost no change in this shadow but the films of October 3 showed an increase in parenchymal density.

The patient was admitted to the University Hospital on October 18, 1946. No physical findings of

importance were found except in the region of the pulmonary lesion. No mass was felt in the renal regions, the blood pressure was 140/86, but there was no evidence of cardiac disease and an electrocardiogram was not outside the normal limits.

Bronchoscopy was performed by Cameron Haight on October 21; no neoplasm could be seen as was also so when bronchoscopies were carried out on July 7, August 23, and October 4. Haight removed the right lung on October 25, 1946. The upper lobe was densely adherent anterolaterally. A 5 centimeter diameter yellowish neoplasm was present centrally in the upper lobe. A 1 centimeter nodule was present in the apex of the lower lobe and there were several similar nodules in the upper lobe. Bronchiectases occupied that part of the upper lobe whose bronchus was obstructed by a neoplastic nodule. A 1 millimeter nodule was removed from the parietal pleura near the neoplasm. Dr. A. J. French of the Department of Pathology reported this as being a malignant neoplasm, probably carcinoma, but control sections did not show any malignancy. Dr. R. C. Wanstrom reported that the pulmonary neoplasm was a widely infiltrating metastatic hypernephroma; there was no involvement of the bronchial lymph nodes.

Two days after operation a sudden jump in the pulse rate to 170, for which no extracardiac explanation was available, caused the making of an electrocardiogram which showed marked notching of the P waves suggesting an auricular change. Two days later an electrocardiogram showed auricular flutter with a ventricular rate of 188 and an auricular rate of 376 or possibly paroxysmal tachycardia with a 1 to 1 response. The following day after digitalis the pulse rate was 108, the electrocardiographic diagnosis was unchanged. All the electrocardiographic interpretations were made by Dr. Frank N. Wilson. On November 25, 1946, 1 month after operation the temperature was normal, the pulse approximately 110 and the patient was in a moderately satisfactory general condition. Several days before when the digitalis dosage was temporarily reduced the auricular fibrillation returned. This case is added to the series so soon after operation only because the series includes all cases known to us in which both the primary and initial metastatic pulmonary lesions have been removed. The ultimate prognosis seems poor because there were several nodular neoplasms in addition to the chief neoplasm in the right lung.

SUMMARY

1. The appearance of a solitary metastatic lesion in a lung months or years after the removal of a primary extrapulmonary sarcoma or carcinoma is far from rare.

2. Only 5 adequate case records showing the results of the resection of the metastatic pulmonary lesion have been published. Nine teen additional records are included in this article.

The records of D. Samson, second and third patients, both of whom were operated upon recently, were not available when this article was completed.

3 One of the 24 patients died as a direct result of the pneumonectomy or lobectomy operations. Eleven have had recurrence of the neoplasm and 12 have had no recurrence

4 Among the 12 patients with no recurrence 8 are apparently well 12 7 6 5 4 3 $1\frac{1}{4}$ and 1 years respectively after the pulmonary resection operations. Four patients were operated upon too recently for evaluation

5 Six of the 8 sarcoma patients but only 6 of the 15 carcinoma patients (excluding the 1 who died as a result of operation) are apparently free of recurrence. Two of the 6 sarcomas and 2 of the 6 carcinomas, however were operated upon less than 10 months ago. Four renal cell carcinoma patients (including 1 operated upon a month ago) are free of recurrence. Only 2 other carcinoma patients are free of recurrence one 3 years and the other $3\frac{1}{2}$ months after pulmonary resection

THE DIAGNOSIS OF ABDOMINAL TRAUMA IN WARFARE

C. G. ROB M.C., M.Chir., F.R.C.S., Late Lieutenant Colonel Royal Army Medical Corps,
London England

MANY papers have been written on the treatment of the abdominal gunshot wound but the diagnosis has received less attention. In my opinion a careful preoperative examination and diagnosis in these cases is amply justified by the number of lives saved. During the first 6 months of 1944, 560 laparotomies were performed on British battle casualties in Italy. A visceral lesion was not found in 66 (12%) of these cases and of these 66 29 per cent died the unnecessary laparotomy being a major cause of these 19 deaths. During the same period 50 laparotomies (9% of the total cases) were performed for a wound of the liver or kidneys only. While in some of these full abdominal exploration was necessary for the control of hemorrhage, I would emphasize that with a more accurate diagnosis laparotomy should not have been necessary in the majority. A similar high incidence of negative abdominal exploration has occurred in other theaters of war (Table I). The importance of avoiding an unnecessary laparotomy in battle casualties is absolutely imperative; the attitude of "let's look and see" has no place in field surgery until a full clinical examination and sound diagnosis has been made.

This paper is based on 172 cases in which patients were admitted to and treated at an advanced surgical center in Italy. For about half of them the location was a field dressing station where no x-ray apparatus was available for the remainder a casualty clearing station with its added facilities including an x-ray plant. The average time at which operation was performed was 6.4 hours after wounding. All patients were retained for a minimum of 10 days the majority for longer but the follow-up has been incomplete. However no patient was evacuated until on a full diet his

TABLE I.—THE INCIDENCE OF A POSSIBLY UNNECESSARY LAPAROTOMY

bowels acting regularly and the peritoneum clinically free from residual abscesses. The only exceptions were 3 patients with pelvic abscesses who had to be evacuated before the abscesses had resolved and these are known to have recovered.

All the 172 admissions showed marked and definite clinical abdominal symptoms and signs and in all a diagnosis had been made by a medical officer of a penetrating wound of the abdomen. Of these 172 patients 6 (3.5%) were brought in dead or were moribund on ad-

TABLE II.—ANALYSIS OF 166 CASES WITH DEFINITE ABDOMINAL SYMPTOMS AND SIGNS

	Cases
1. <i>Laparotomy performed</i> (Deaths 39)	113
a. Necessary (wounds of the hollow viscera or wounds of the solid viscera in which hemorrhage necessitated laparotomy)	103
b. Unnecessary	1
Liver or kidney only	0
Retroperitoneal tissues	2
2. <i>Laparotomy not performed</i> (wound excision only) (Deaths 1)	53
a. Extraperitoneal hematoma	14
b. Thoracoabdominal or abdominal wound with a hemoperitoneum (liver or kidney only)	0
c. Chest wound with abdominal signs	7
d. Buttock wound with a fractured pelvis	6
e. Kidney wound (without a hemoperitoneum)	4
f. Localized peritonitis in a wound more than 36 hours old	4
g. Extraperitoneal wound of the bladder	3
h. Spinal wound with paraplegia and hyperesthesia	3
i. Blast injury	2
j. Colon (extraperitoneal only)	1

Resident Assistant Surgeon, St. Thomas Hospital, London.
Hinterland Lecture delivered at the Royal College of Surgeons,
May 20, 1946.

mission and died at a very early stage of resuscitation the remaining 166 (96.5%) were operated upon.

It may be seen with the aid of Table II that

a. In 113 patients a laparotomy was performed, and in 53 a wound excision without abdominal exploration.

b. Over half of these patients had other wounds in addition to those involving the abdomen, and in 50 per cent these were of first priority degree in themselves.

c. There were 40 deaths in this series.

d. There were 39 deaths among the 113 patients who had a laparotomy and only 1 death among the other 53 patients in whom I elected not to open the abdomen.

e. Of the 39 patients who died after laparotomy 17 had associated first priority lesions such as extensive muscle wounds, gas gangrene, traumatic amputations, major fractures cerebral wounds, etc. 14 had associated minor wounds in 8 the abdominal was the only wound.

f. Unnecessary laparotomies were performed in 11 of which 9 (8% of the total laparotomies) were for liver or renal wounds, and 2 (2% of the total laparotomies) were for injuries to the retroperitoneal tissues. The criterion taken for an unnecessary laparotomy has been one in which nothing except exploration was done, and in which recovery followed.

g. Of the 53 patients treated without laparotomy 13 (25%) had intraperitoneal lesions and of these every one recovered. The remaining 40 (75%) had wounds of the structures in close relationship to the parietal peritoneum of these one, a spinal wound with paraplegia and abdominal hyperesthesia, was the only patient who died.

h. In 34 patients there was a wound of the liver either with or without an associated visceral lesion. In only one of these was surgery necessary for the control of hemorrhage.

i. In 22 patients there was a renal wound either with or without an associated visceral lesion. In only 3 of these was nephrectomy necessary.

The effects of other wounds on the mortality of abdominal surgery in war is marked. In a series published by Lieutenant Colonel Guy Blackburn and myself the mortality for abdominal wounds without other first or second priority wounds was 25 per cent but in association with these wounds it was 42 per cent.

DIAGNOSIS

It is essential to see the wood as well as the trees, by which is meant that a general survey of the patient is the first consideration. What is the state of the peripheral circulation?

What is the blood pressure and the pulse pressure? What is the pulse rate?

Practically every patient has already been given morphia to allow him to undertake the journey back. With increasing experience and in spite of a considerable reduction of abdominal pain and rigidity an accurate diagnosis can still be made in these heavily morphinized patients.

Further factors to be considered are

1. The state of dehydration of the patient. The majority of patients with war wounds of the abdomen are dehydrated when seen.

2. Resuscitation usually takes a matter of some hours, which enables the surgeon to review the case on more than one occasion. This is important because the clinical picture varies from hour to hour. And I would here mention that a valuable diagnostic pointer is given by the fact that most patients with out a lesion of the alimentary tract either do not require resuscitation or respond rapidly. An exception may be made by cases with severe hemorrhage or associated other first priority wounds.

3. Age. In this series age ranged from 17 (that of a German prisoner of war) to 40.

4. Fighting fit soldiers usually have an abdominal wall of high muscle tone which in itself is a trap for the unwary.

5. Owing to the mixed racial composition of the Allied Armies in Italy marked differences of temperament had to be evaluated.

There is no difficulty of diagnosis in many patients they may show an abdomen with the general rigidity and tenderness, the absence of respiratory movements and the silence on auscultation of general peritonitis or there may be a prolapse of viscera through the wound. The problem arises in the less obvious case and before discussing individual lesions there are two physical signs of fundamental value in all cases. These are (1) an efficient clinical estimate of the wound track and (2) auscultation of the abdomen.

A CLINICAL ESTIMATE OF THE WOUND TRACK

A clinical estimate of the wound track can be obtained by the following

1. *The preoperative appearance of the wounds* including the relationship of the exit wound if present to the wound of entry and a statement from the patient as to the posture he was in when hit. This latter is important and explains many unusual wound tracks. It has

been my experience that missiles take a straight course from one point to another unless deflected by bone. I well remember a patient with a wound just above the right inguinal ligament and the foreign body lying in the right ischium. At operation the only lesion found was a laceration of the hepatic flexure of the colon, and subsequent inquiry elicited the fact that he had been bending to adjust his boot when wounded.

2 *The usual routine clinical examination*, particular attention being paid to those symptoms and signs of localizing diagnostic significance.

3 *Rectal examination and catheterization* have been of importance in tracing the track of many missiles.

4 *A radiological examination*, when available to locate foreign bodies and to demonstrate fractures. This has been of most value in wounds of the upper abdomen and lower chest where the foreign body may be located in the liver or thorax, wounds of the buttock where the foreign body may be retained in a fractured ilium, and wounds of the extraperitoneal regions.

5 *The findings at wound excision* which has been performed in every case. When patients are fit for the theater and whether laparotomy is to be performed or not. I first of all excuse every wound which might have penetrated the peritoneum. *This is essential and in my experience exploration of the wound track in the operating theater has often been the deciding factor for or against opening the abdomen.*

AUSCULTATION OF THE ABDOMEN

It is important to ascertain the presence or absence of peristaltic sounds. These may be mimicked by sounds due to a fluid gas mixture in the bowel itself particularly when the gut is distended. These can be reproduced by rolling the patient and listening at the same time but with experience there is no difficulty in differentiating them from peristaltic sounds. Auscultation of the abdomen has been performed on every case in this series, when necessary on more than one occasion and for 2 or 3 minutes at a time until the presence or absence of peristalsis has been established beyond doubt.

In an analysis of abdominal auscultation in a total of 166 cases, the following was noted:

In the presence of a lesion of a hollow viscus peristalsis was present in 6 absent in 89. In the absence of a lesion of a hollow viscus peristalsis was present in 70 and absent in 1.

Thus in only 1 per cent of those patients without a hollow visceral lesion was peristalsis absent in this patient who had a large posterior extraperitoneal hematoma the abdomen was silent throughout. Laparotomy in this case was one of the two unnecessary laparotomies performed for extraperitoneal hematomas. However in those patients with a lesion of a hollow viscus, 94 per cent had no peristaltic sounds. In 2 patients with small intestinal wounds 3 patients with wounds of the colon and 1 intraperitoneal wound of the bladder peristalsis was heard. In these there was little leakage from the bowel and minimal peritoneal soiling and I am convinced that peristalsis is only absent when the activity of all the intestine has been inhibited by a general peritoneal soiling although before this a local silence occurs immediately around the perforation. The following patient seen in consultation with Lieutenant Colonel A. J. Latchmore, R.A.M.C. illustrates this point well.

Patient had received a machine gun bullet wound 2½ hours before admission. The bullet's entry was anteriorly just to the left of the midline at the level of the sixth rib and its exit at the level of the 10th rib in the posterior axillary line of the same side. The abdomen was tender but soft peristalsis could be heard as the patient was very distressed he was sat up. Immediately he complained of great abdominal pain, so after 5 minutes he was laid down again. On examination the abdomen now had generalized rigidity and tenderness with complete silence on auscultation. At operation a large tear of the stomach was found. It appears that when this patient sat up his gastric contents, which previously had been localized to the upper left abdominal quadrant were spread rapidly over his entire peritoneum thereby producing the sudden change of abdominal physical signs.

Therefore I submit that the absence of peristaltic sounds confirmed and reconfirmed is a positive indication for laparotomy but that the presence of peristaltic sounds is only a valuable guide toward and not a positive indication for conservative treatment.

FURTHER DIAGNOSTIC POINTS

Certain points have been of particular help in the various case groups.

Extrapertoneal hematoma When in the anterior abdominal wall the rigidity and tenderness have been localized to the wounded region and occasionally there is local surgical emphysema due to respiratory movements sucking air along the wound track, the foreign body may be palpable but if the wound is through and-through as it often is in the loin the possibility of a rupture of the intestine even with an intact peritoneum must be considered if the missile is a bullet. Occasionally these hematomas are large as when the deep (inferior) epigastric artery has been injured.

Posterior extraperitoneal hematomas have been diagnosed by the mild rigidity if light palpation is employed and by the presence of peristaltic sounds. Tenderness, however may be extremely great over the localized area of the hematoma, and peristaltic sounds are themselves sometimes faint and require patience to detect. In these cases the possibility of missing an extraperitoneal tear of a fixed portion of the intestine has been avoided by a careful wound excision and exploration. In cases seen late ileus distention may be marked.

In pelvic extraperitoneal hematomas rectal examination both digitally and with a proctoscope has been invaluable for while tenderness may be deceptive due to extraperitoneal bruising it is by this measure alone that a peritonitis of the rectovesical pouch can be diagnosed before it has spread to the general peritoneal cavity these cases are usually associated with buttock wounds and fractures of the pelvic bones. On two occasions wound and wound track excision and exploration were followed by an extraperitoneal exploration above the inguinal ligament and removal of a foreign body from the pelvic fascia in one of these the termination of the descending colon was lacerated extraperitoneally and suture with drainage but without laparotomy was successful.

Wounds of the liver It has been my experience that of 34 such patients in only one was surgery necessary for the control of hemorrhage. These cases of simple hemoperitoneum form a large and important group of abdominal war wounds, because they are one of the

few intraperitoneal lesions in which laparotomy is not necessary. An x ray film is invaluable when the foreign body has been retained, as an adequate estimation of the wound track may be impossible without one. In the majority of the unnecessary laparotomies of this series the course of the missile could not be estimated because an x ray machine was not available. The presence of some abdominal wall movement with respiration, of a mild rigidity on light palpation and of peristalsis by abdominal auscultation have all aided the diagnosis. In no case where the liver was the only lesion was peristalsis absent although in several patients a large and diffuse hemoperitoneum was present. These patients have been watched very carefully for further bleeding but in only one case did this necessitate operation. I would remind you of the ease with which hemorrhage from the liver may be restarted by the laparotomy itself and in some cases of the extreme difficulty of controlling it again.

Wounds of the kidney War wounds differ in many respects from the closed traumatic injuries of civilian practice. In the former one does not see the large swelling of the perinephric tissues nor does one meet the typical pain and colic at an advanced surgical center although the last named has been noted during convalescence. On palpation local tenderness and rigidity can be elicited. Catheterization is essential for without exception in this series hematuria has been present. At operation wound excision and exploration will show the track of the missile and the opportunity is taken for accurate palpation of the kidney. As a result of this palpation an estimate can be made as to the necessity for nephrectomy and it has been my experience that the majority can be treated expectantly. In this series of 22 renal wounds only 3 required immediate nephrectomy. It is possible that in some cases removal of the kidney is done at a later date but such patients are better fitted then to stand the operation. Various reconstructive operations have been recommended for these renal lacerations, but in field surgery they are unsafe and the immediate results of simple drainage appear to be very satisfactory.

Wounds of the ureter I myself have met no case of injury to either ureter distal to the renal pelvis.

Bladder wounds are either intraperitoneal or extraperitoneal. The fact that the bladder has been injured rarely presents difficulty in diagnosis. Occasionally due to a wound of the abdominal wall it may be impossible to tell by abdominal examination whether the bladder is full or empty. In these cases a rectal examination and catheterization will solve the problem. But when the bladder is the only visceral lesion an intraperitoneal rupture may not be found before the wound has been explored. Suprapubic cystostomy has to be performed on both groups and this procedure combined with drainage of any extraperitoneal urinary extravasation provides an ideal opportunity for assessing the damage.

Chest wounds with abdominal signs If there is only an entry wound present in the thorax an x ray film is invaluable to determine the relationship of the foreign body to the diaphragm. With the portable x ray apparatus available in forward areas a lateral film although essential, is unsatisfactory. Screening is impossible and reliance has to be placed on the anteroposterior film alone. On the right side this is of little moment because if the foreign body is just below the diaphragm it will be in the liver. However on the left side the diagnosis may have to rest on a full clinical examination. If there is a continued absence of peristalsis the foreign body has injured a hollow viscus. When the chest alone is injured there is usually some abdominal breathing, abdominal tenderness is slight and rigidity located only on the side of the chest wound. It is generally mild, relaxes with respiration and tends to abate with rest. A correct diagnosis should be possible in all these cases.

Wounds of the buttocks These form one of the more common wounds of this war. When the track penetrates the peritoneal cavity there is a considerably higher mortality than with abdominal gunshot wounds via other routes (1). Unusual wound tracks are commonly encountered from this region usually due to posture and to the fact that the buttock forms a pivotal point between the trunk and

lower limbs. As a result it is not unusual for the foreign body to be found as low as the knee or as high as the shoulder. An x ray film is of obvious importance for the location of these missiles and when the foreign body has fractured the pelvis the film must be carefully inspected so that bone fragments which may have been driven into the peritoneal cavity are not missed. I have had a case in which the colon was perforated by a spicule of ilium. These wounds should be under very strong suspicion until a very careful clinical examination has excluded damage to the alimentary or urinary tracts. The importance of localized abdominal rigidity, rectal examination, proctoscopy and catheterization has already been stressed. Gas gangrene is an ever present danger and a thorough wound excision must be carried out.

Spinal wounds with abdominal hyperesthesia Such patients if seen early present no special difficulty of diagnosis. It is those patients seen late when abdominal distention has occurred who present the problem. Should a laparotomy be performed? What are the points of differential diagnosis? The ileus distention of spinal wounds comes on much sooner than the distention of general peritonitis. In a spinal cord lesion tenderness and hyperesthesia are localized to the segment just above the paralyzed level, on the other hand rigidity like pain is a sign of doubtful value in the diagnosis. Peristalsis may be very faint in these cases but in this series it has always been present. Paraplegia, because of its possible association with an abdominal visceral lesion has no value in the differential diagnosis. Priapism has been noted in these cases but I have never seen it with an extraperitoneal hematoma.

Late wounds Patients seen more than 36 hours after visceral perforation differ but little from similar disasters of civilian practice. Four patients had lain on the battlefield for long periods and upon admission showed localized abdominal signs, findings similar to that presented by an appendix mass. The lesions were thought to be of the colon only and they were treated without laparotomy. Subsequently 3 developed a local abscess which required drainage and of these 2 had a temporary fecal fis-

tula. In this series there were a further 8 late cases all admitted with advanced generalized peritonitis and desperately ill. Of these 3 were opened and closed again immediately as their general condition would not stand the multiple visceral repairs necessary. In the 5 remaining all their abdominal lesions were surgically treated but 3 of these died later. The value of massive doses of plasma in these cases of general peritonitis is enormous. In my opinion this therapy counteracts the circulatory failure which is due to plasma loss from the inflamed peritoneum, the surface of which is equal to that of the whole body.

Extrapertoneal wounds of the colon In patients seen early an extraperitoneal wound of the colon can be diagnosed only at wound excision.

Blast injuries Naval warfare provides far more cases of abdominal blast injury than does military. They may present an extremely difficult diagnostic problem and I want to quote in detail the 2 cases of this series.

The first man, a gunner, had a cannon shell wound of the back and left chest; there were very marked abdominal signs including absence of peristaltic sounds. Resuscitation was commenced, and later on one occasion only I heard very faint peristalsis. In view of this no laparotomy was performed, the chest wound only being treated, and he recovered.

I have no doubt that his abdominal signs were due to the blast effects of the explosive cannon shell.

The second case, an officer, was riding when his horse trod on a Teller mine. The horse was blown to pieces but the officer escaped with severe multiple injuries, and he was in abdominal distress. When I saw him 3 hours after injury, there was a traumatic amputation of one leg at the knee, a compound fracture of the opposite femur, generalized multiple wounds, and his abdomen was rigid and silent. His condition would not have allowed excision of all the small wounds, several of which might have penetrated into the peritoneum. After resuscitation, peristalsis was heard and in view of this, I decided not to perform a laparotomy. I performed an amputation of one leg, excised the wounds and splinted the other and he recovered. A laparotomy in addition most certainly would have killed him.

In neither of these cases was an x ray machine available, and the presence of perforated ear drums was taken as evidence that blast lesions had occurred.

Patients moribund on admission Six patients (3.5% of the total) were dead or moribund on admission: 3 from severe multiple injuries, 2 from thoracoabdominal wounds and only 1 from an abdominal wound alone. The thoracoabdominal wounds are of interest because there were 2 of the 3 cases of *diaphragmatic hernia* seen; both had extensive herniation and the diagnosis was easy as the abdominal viscera were presenting through the thoracic wound. The third patient recovered and the diagnosis was made by the presence of peristalsis within the chest, the herniated viscera not being perforated.

I have already emphasized earlier in this paper the extreme difficulty that many cases cause in diagnosis. These patients reach an advanced surgical center heavily morphinized and often without abdominal pain. Because of this an abdominal lesion may be completely missed, a possibility which must be continually guarded against. The problem arises when the wound of entry is at some distance from the abdomen and is most commonly found in association with a wound of the thigh, buttocks, or even the neck. The following 2 cases illustrate some of the difficulties.

An Indian soldier was brought to me with the diagnosis of prolapsed viscera. When I saw him it was obvious that an intact peritoneum was ballooning through a gutter wound which had divided both recti abdomina. In spite of this he had the physical signs of a perforated hollow viscus. At operation excision of this gutter wound confirmed the presence of an intact peritoneum, and it was only then that I discovered a small wound of the right loin. This wound penetrated the peritoneum and the small intestine was perforated.

A German medical officer was wounded by a machine gun bullet, which had fractured his right shoulder and produced a right hemothorax. Although a qualified doctor he made no complaint of abdominal pain. The availability of an apparatus enabled an x ray film of the chest to be taken, and it was only when this demonstrated the bullet to be below the diaphragm that the possibility of an abdominal lesion was considered. Although he still complained of no abdominal pain, clinical examination showed in point of fact that he had a perforated hollow viscus. At operation I removed the bullet from the epigastrium and sutured a laceration of the fundus of the stomach.

On the other hand pain in the legs may be the major symptom, when the lumbar plexus

has been involved in association with visceral damage

Some of the symptoms and signs which are standard in civil practice have been of little value in the gunshot wound due to a number of factors including the longer time lag and the more disturbing evacuation. I have already mentioned the variability of abdominal pain which may be masked by morphine and shock or overshadowed by the pain of other major wounds. In some cases patients have complained of abdominal pain when peritoneal penetration had not occurred. For example the pain of a retroperitoneal hematoma may be very great. The shoulder tip pain of diaphragmatic irritation has been noted in only 8 patients although a leading question has been put to every English-speaking patient. Except with spinal cord lesions morphine had rendered valueless the testing for abdominal hyperesthesia.

In civilian practice rigidity is a sign which has great significance but its value has been considerably less in the gunshot wound and an entirely false diagnosis may be made if too great reliance is placed upon it. The boardlike rigidity of a perforated peptic ulcer although it may occur is uncommon. Rigidity too may be marked with wounds of the chest, abdominal wall or buttocks while in early cases with intestinal perforations it may be absent.

Abdominal percussion will demonstrate shifting dullness on the other hand the sign of absence of liver dullness is valueless. Four cases of simple liver wound showed a diminution of liver dullness presumably due to entry of air along the wound track. For the same reason an x ray film of the abdomen to show gas between the liver and the diaphragm has been of no help. Vomiting may occur in all wounds and unless the vomitus has distinguishing characteristics such as the presence of blood the diagnostic value has been slight. Bleeding per rectum is of obvious importance but bowel actions and the passage of flatus have been without significance. Examination has often revealed a dry furred tongue without an abdominal wound and urine analysis beyond a search for blood has not been performed.

PLANNING THE LAPAROTOMY INCISION

Correct planning of the laparotomy incision is invaluable. While the greater part of the small intestine can be examined through all abdominal incisions this is not so of the other viscera. The most reliable sign for planning the incision has been an estimate of the wound track but other signs such as hematuria, the vomiting of blood and localized rigidity and tenderness have been of value. In wounds of the right or left colon an oblique flank incision saves further soiling of the general peritoneal cavity and allows inspection of the adjacent viscera. The importance of a correct assessment of all the diagnostic facts before siting the incision and the difficulties encountered through ignoring them are well exemplified by the only case in which I missed a visceral perforation.

I operated upon a British soldier 3 hours after wounding. There were 3 penetrating wounds of the abdomen centered around the umbilicus, with the signs of general peritonitis and a history of hematemesis. I performed a laparotomy through a right mid-paramedian incision sutured 8 perforations of the small intestine, and exteriorized a lacerated loop of transverse colon. I found no obvious lesion of the stomach. This man died after 2 days from general peritonitis and postmortem examination revealed a high perforation of the stomach.

In this case if greater attention had been paid to the history of the vomiting of blood an upper paramedian incision would have been made and the gastric perforation found and closed.

Before I conclude my remarks on diagnosis there are two further points requiring discussion.

First Brigadier Charles Donald has suggested making a small abdominal incision and inserting a swab on a holder into the pelvis. If it is blood-stained then laparotomy is performed. I feel that this does not go far enough because it does not distinguish between a simple hemoperitoneum which might be treated without laparotomy and a perforated hollow viscus which requires an immediate laparotomy.

Second it has been stated that a through and through wound between the linea semi lunares does not penetrate the peritoneum. While this is probably true for fit soldiers I

have had a case of an Italian civilian female in which such a wound produced multiple intestinal perforations due undoubtedly to her pendulous abdominal wall

CONCLUSION

The mortality from unnecessary laparotomy demands the greatest care and accuracy in the diagnosis of the abdominal gunshot wound. Although I have stressed the great value of abdominal auscultation and wound exploration no single sign or group of signs should be relied on without a full and careful clinical examination of the patient as a whole

Finally where a genuine doubt exists after repeated examinations it is advisable to open the abdomen but these exploratory laparotomies should rarely be necessary

PLASMA CLOT GRAFT OF PERITONEUM FOR PERFORATIONS OF STOMACH

Preliminary Report of an Experimental Study

JOSEPH BLOOM M.D. New York New York

THE purpose of this study was to see if it were possible to close a perforation of the stomach with a graft of peritoneum by substituting plasma clot for sutures. Occasionally the surgeon finds a perforated peptic ulcer with extensive induration or a perforated ulceration through a carcinoma so extensive that he is at a loss as to what to do. This type of perforation usually does not lend itself to suture closure because of induration. He might attempt primary resection in the face of infection but he knows how greatly this increases the risk to the patient. He has attempted in the past to cover the perforation with neighboring organs but this step frequently fails to give a tight closure and the patient expires from a peritonitis despite treatment. However if he could tide his patient over the critical period of perforation he could get him into better physical condition for more extensive surgery if it is indicated later on. The method that will be described is intended for this purpose to tide the patient over the acute period of perforation so that the peritoneum can more easily combat the infection due to leakage as well as stop the leak for the time being. No evidence has thus far been obtained on human patients since no attempt has yet been made in this direction. The present paper is only a preliminary report of the more extensive investigation that is contemplated.

In 1896 William H. Bennett described a method of attacking this problem by the use of an omental plug. He encountered a perforated gastric ulcer in which the area of induration was 3 inches in diameter and the perforation a half inch in diameter. He was unable to suture it so he pulled up the omentum and

after inserting a portion of it into the orifice, sutured it into position by a through and through stitch tacking the rest of the omentum about it. The patient recovered.

In 1927 Martin and Rogers using balloons studied the hunger contractions of the stomach. They demonstrated the phenomenon of circular constriction of the lower third of the stomach. They showed that this also took place in the antrum with a general shortening of the stomach separating periodically the fundus body and pars pylorica. This is quite similar to what takes place in the small intestine. Parkas Gruber showed that proximal dilatation and distal contraction take place in the body while proximal contraction and distal dilatation take place in the pars pylorica of the stomach.

Although it is well known that the stomach has 3 sets of muscle fibers that produce contractions there exists a small area on the lesser curvature of the prepyloric region at the level of the incisura angularis extending for 1 to 2 centimeters, which is almost without longitudinal fibers. This is the most frequent site of perforation for prepyloric ulcers. For this reason Forsell calls it the membrana angularis. The predominating muscular fiber development at the prepyloric and pyloric region is therefore the circular fibers (5). These produce contractions at right angles to the long axis of the stomach and duodenum. It appears logical to assume that in closing a perforation at this point by suture methods only sutures placed at right angles to the circular fibers will be effective and they must always include these fibers. However since this is dependent upon the presence of such holding fibers the extent of disease when very great precludes the use of this tissue in suturing. A graft closure therefore which does not require the use of sutures should succeed more frequently than

PLASMA CLOT GRAFT OF PERITONEUM FOR PERFORATIONS OF STOMACH

Preliminary Report of an Experimental Study

JOSEPH BLOOM, M.D., New York, New York

THE purpose of this study was to see if it were possible to close a perforation of the stomach with a graft of peritoneum by substituting plasma clot for sutures. Occasionally the surgeon finds a perforated peptic ulcer with extensive induration or a perforated ulceration through a carcinoma so extensive that he is at a loss as to what to do. This type of perforation usually does not lend itself to suture closure because of induration. He might attempt primary resection in the face of infection but he knows how greatly this increases the risk to the patient. He has attempted in the past to cover the perforation with neighboring organs but this step frequently fails to give a tight closure and the patient expires from a peritonitis despite treatment. However if he could tide his patient over the critical period of perforation he could get him into better physical condition for more extensive surgery if it is indicated later on. The method that will be described is intended for this purpose to tide the patient over the acute period of perforation so that the peritoneum can more easily combat the infection due to leakage as well as stop the leak for the time being. No evidence has thus far been obtained on human patients since no attempt has yet been made in this direction. The present paper is only a preliminary report of the more extensive investigation that is contemplated.

In 1896 William H. Bennett described a method of attacking this problem by the use of an omental plug. He encountered a perforated gastric ulcer in which the area of induration was 3 inches in diameter and the perforation a half inch in diameter. He was unable to suture it so he pulled up the omentum and

after inserting a portion of it into the orifice sutured it into position by a through and through stitch, tacking the rest of the omentum about it. The patient recovered.

In 1927 Martin and Rogers, using balloons studied the hunger contractions of the stomach. They demonstrated the phenomenon of circular constriction of the lower third of the stomach. They showed that this also took place in the antrum with a general shortening of the stomach separating periodically the fundus body and pars pylorica. This is quite similar to what takes place in the small intestine. Tarkas Gruber showed that proximal dilatation and distal contraction take place in the body while proximal contraction and distal dilatation take place in the pars pylorica of the stomach.

Although it is well known that the stomach has 3 sets of muscle fibers that produce contractions there exists a small area on the lesser curvature of the prepyloric region at the level of the incisura angularis extending for 1 to 2 centimeters which is almost without longitudinal fibers. This is the most frequent site of perforation for prepyloric ulcers. For this reason Forsell calls it the membrana angularis. The predominating muscular fiber development at the prepyloric and pyloric region is therefore the circular fibers (5). These produce contractions at right angles to the long axis of the stomach and duodenum. It appears logical to assume that in closing a perforation at this point by suture methods only sutures placed at right angles to the circular fibers will be effective and they must always include these fibers. However since this is dependent upon the presence of such holding fibers the extent of disease when very great precludes the use of this tissue in suturing. A graft closure therefore which does not require the use of sutures should succeed more frequently than

Fig. 1. First stage of experiment. Artificial perforation with cautery.

any type of suture closure. It appears logical to assume that from the mechanical view point, a successful graft closure using an adhesive method instead of sutures would operate independently of the anatomical distribution of the muscular layers of the stomach.

Sano in 1943 used a sutureless technique to hold skin grafts in place. His method utilized dried plasma and leucocyte cream. His grafts were completely fixed in 4 days.

Cannaday in 1943 employed strips of skin in repairing hernial defects and no ill effects came from hurrying skin in soft tissues. He also used a thromboplastic method.

Young and Favata, in 1944 used thrombin solution on unwashed skin graft and normal pooled plasma on the recipient area.

In 1946 John Devine, an Australian described the use of peritoneal grafts as a seal to prevent leakage after intestinal anastomosis by suture.

Price and Lee in their observations of gastric digestion on living tissue found that there is a great variation in the susceptibility of living tissues to gastric digestion. In the order of their susceptibility they found first the seromuscular coats of the intestine and gall bladder omentum cartilage, kidney spleen lung liver and pancreas. The most resistant of all are fibrous connective tissue skin and gastrointestinal mucosa.

The present experiment utilized as the graft of choice, a combination of peritoneum and

Fig. 2. Second stage of experiment. Perforation plugged with cycol and covered with peritoneal fascial graft. Schematic representation of cross section.

fascia, as found in the posterior rectus sheath, to either side of the midline. The grafts used were taken at that point where the posterior rectus sheath and peritoneum are fused almost inseparably.

EXPERIMENTAL METHOD

In order to simulate the induration of a perforated ulcer in the experimental animals, the perforations were produced with cautery the heat producing a white coagulated area about the perforation and searing the edges of the perforation.

Nine dogs were used in the experiment. It was felt that if a graft held under clean experimental conditions without the presence of infection then further attempts should be made in the presence of active disease.

The size of the perforation was given considerable thought. If too small, then our purpose would be defeated as it might then close by itself. If too large, then an autogenous graft of peritoneum of adequate size could not be taken from the animal safely. It was decided to produce with cautery a perforation 0.625 centimeter in diameter through the stomach wall in the prepyloric or in the duodenal area and cook the surrounding tissue so that the perforation would remain open.

All animals were opened through an upper midline incision about 5 centimeters long. The anesthesia for all animals was intraperitoneal nembutal the amount varying from 2 to 4 cubic centimeters of a solution of nembutal consisting of 1 grain per cubic centimeter of a 10 per cent alcoholic solution. The amount given was on the basis of 1 cubic centimeter per 5 pounds of weight in each animal. Comparatively small animals were used.

Experimental dog was perforated on the anterior wall of the stomach in the prepyloric area. The

Fig. 3. Drawing showing the external appearance of the fascial-peritoneal graft in place after application of the plasma clot and pressure.

Fig. 4. Healed appearance of the serosal surface of the stomach 1 month after healing by plasma clot graft, over perforation. This healed area can be seen in Figure 5 after section and microscopic study.

patch of fascia peritoneum 2.5 centimeters long and 1.25 centimeters wide was taken from behind the left rectus muscle. The serosa of the stomach wall was moistened with a few drops of human plasma, while the graft was moistened on the peritoneal surface with bovine topical thrombin solution, 1:5000. The graft was then spread out over the perforation and allowed to remain there for 3 minutes. The abdomen was then closed in layers cotton suture material being used throughout. This animal died 24 hours postoperatively. Postmortem examination revealed no free fluid in the peritoneal cavity and no visible exudate. The graft still remained in place over the perforation but one small edge was loosely adherent at one point and may have leaked sufficiently to cause death, apparently from peritonitis.

Experimental dog 2 was operated on under the same conditions. This time the graft was applied after the gastric serosa was moistened with human plasma. A hypodermic needle was then inserted beneath the graft and the topical thrombin was injected under it in a fanwise manner. This graft was 1.25 by 1.25 centimeters in diameter. The animal appeared alive and well for 5 days and was sacrificed to determine the extent of healing. It was discovered that the graft had slipped 2.5 centimeters from the original site of perforation but that the perforation had become covered by the liver sufficiently enough to prevent for the time being a spill and subsequent peritonitis. The fascial peritoneal graft however had become adherent to the serosal surface of the stomach 2.5 centimeters away.

Experimental dog 3 was operated on in the same way. A graft 1.5 by 1.87 centimeters was placed over the perforation. Plasma and topical thrombin were again used as an adhesive agent. This animal died 24 hours postoperative of a fulminating peritonitis. Postmortem revealed the fact that the graft had

completely slid off the stomach wall and lay free in the peritoneal cavity permitting the gastric contents to pour through the perforation quite freely. The graft was found to have a pale appearance as though it had undergone a bleaching process, perhaps from the digestive action of the gastric juices. The peritoneal cavity was filled with a purulent flaky fluid the intestines were matted together with a plastic like exudate and distended. The perforation was wide open. Nature had not been able to cover this opening with any of the neighboring organs such as omentum, liver, or contiguous intestinal loops.

Experimental dog 4 was subjected to the same procedure except that for the first time, the idea of packing the perforation was introduced. This was done with the use of oxidized cellulose gauze. The excess after filling the perforation, was then cut off flush with the gastric serosa, and the human plasma placed on and around the plug. The graft was then placed over the perforation and topical thrombin was squirted beneath it with a syringe. The animal died on the eighth postoperative day. Another variation was attempted at the time of operation upon this animal in that the usual fascial peritoneal graft was not taken. In this case, a strip of the falciform ligament of the liver was removed which was quite thick. It appeared quite vascular and more dense than omentum but was very fatty in appearance and structure. Postmortem findings showed death due to peritonitis. The perforation had leaked past some of the plug. Most of the latter however had remained undisturbed in the perforation but had turned a soft mushy green with gastric juice oozing out from along side of it, at one point. However there was no sign of the fatty patch from the falciform ligament. It may have been completely digested but because of the purulent exudate filling the peritoneal cavity this could not be determined objectively.

Fig 5 Microscopic section through healing graft 1 month postoperative. The arrow indicates the junction of

the graft with the original serous surface of the stomach. X85.

Experimental dog 5 was operated upon similarly but a fascial peritoneal graft was used over the perforation. Again a plug of oxycel gauze was used in the manner described above. However the fascial peritoneal graft was held in place by a clamp during the procedure for a period of 3 to 5 minutes with the hope that the pressure under direct vision would enhance the adhesive process assuring complete sealing of the graft. This animal was reoperated upon 33 days later and will be described later on when the type and degree of healing over the perforation will be revealed.

Experimental dog 6 was subjected to the same operative technique as dog 5 except that a pressure clamp was used which did not permit complete direct vision of the graft while it was held in place. This clamp failed to hold down the edges of the graft allowing the perimeter to curl up permitting a leak to develop at one edge, thus causing death from peritonitis on the sixth postoperative day.

Experimental dogs 7, 8, 9 all lived for a month or more after the operation described above on experimental dog 5. The graft used in each of these cases was fascia-peritoneum from the posterior rectus sheath aponeurosis, and peritoneum. In addition to the oxycel plug used, the same type pressure clamp was again used, in the same manner. This clamp offered obvious advantages over the opaque metal clamp used on dog 6.

Thus we had 4 dogs surviving 1 month or more after closure of a perforation of the stomach by application of a graft without the use of any type of suturing. It will be noted that the animals that survived all received the same treatment in the application of the graft over the perforation. All had a plug of oxycel gauze placed into the perforation. The graft was applied and held in place by a pressure clamp that permitted direct vision of the entire patch of tissue used in the graft. Dog 5 lived

32 days, dog 7 33 days, 8 36 days and 9 35 days. All these latter animals were either sacrificed or subjected to a partial gastrectomy in order to obtain the gastric specimen for microscopic study of the healing produced.

In sacrificing these animals the factor determining survival time was the selection of a period during which complete healing seemed assured.

The type of healing is seen in the photomicrographs presented. The gross and microscopic features were the same in all animals. Sections of tissue were taken from dogs 5, 7, 8, and 9 after about 1 month or more of healing, some 32, 33, 36 and 35 days respectively after grafting. All slides showed that dense, strong fibrous healing had occurred. In all sections the mucosa had regenerated and spread across the artificially created perforation. Strong fibrous union developed across the serosal and muscular layers, with an increase in thickness of the stomach wall at that point.

In those animals that did not receive pressure to their graft initially all developed some type of leakage or slipping of the graft. Those that had no oxycel plug died in 24 hours, although one animal died after 5 days, living that long only because the liver had covered the perforation accidentally. The oxycel plug allowed dogs 4 and 6 to live 8 and 6 days respectively but if the graft had held, leakage would not have taken place. The purpose of the plug is twofold. It acts as a bulwark against the intra-gastric pressure which tends to blow the graft

off and secondly being of cellulose, it is even more difficult to digest than is fascia. The combination of this cellulose plug and a fascial peritoneal graft appears to hold strong promise in sealing off gastric perforations.

PREFERRED METHOD OF CLOSURE DEVELOPED

1. The perforation should be plugged with oxycel moistened with 1 per cent sodium bicarbonate solution.

2. Pooled human plasma, 1 to 3 cubic centimeters is applied to the serosal surface of the stomach and plug filled perforation.

3. The graft cut from the posterior rectus sheath of the anterior abdominal wall includes peritoneum as well as fascia and aponeurosis. The graft must be large enough to cover the perforation without being placed on stretch and should cover the perforation overlapping the edges far enough to provide adequate surface contact between graft and gastric serosa so as to provide a good adhesive surface. The graft should be moistened with 1 to 2 cubic centimeters of bovine topical thrombin 1:5000 and this moistened side applied to the plasma moistened serosal area on and around the perforation.

4. The surface to be applied to gastric serosa should be the fascial side of the graft.

5. The graft is held in place by the clamp described in the article. This clamp has a flat surface which holds the graft in place spread out flat. This flat surface is transparent and of plastic material fastened to a metal ring clamp by small countersunk rivets. It can take sterilization by pressure boiling without any loss of visibility or wrinkling of surfaces. By its use, it is felt that the edges of the graft are prevented from curling. Curling of the edges may result in an incompletely sealed patch which may work itself loose, just as a blowout patch on an automobile tire. It is held in place by clamp for 5 minutes.

ANALYSIS OF STUDY

The size of the graft is very important. It must cover the perforation and beyond as far beyond at least as the diameter of the perforation, more if feasible. The larger the graft the less likely leakage will take place. It is our impression that autodigestion of the oxycel

TABLE I—SUMMARY OF RESULTS—9 EXPERIMENTAL ANIMALS

	Technique	Result	Cause
Dog	Peritoneal graft, no plug, no pressure	Died—24 hrs.	F. Peritonitis—leak age
Dog	Peritoneal graft, no plug, no pressure	Sacrificed after 5 days	Perforation covered by liver. Graft slipped
Dog 1	Peritoneal graft, no plug, no pressure	Died—4 hrs.	P. It. It. — Leakage
Dog 4	Falldorm ligament graft, oxycel plug used, no pressure	Died 8 days post operati	Graft slid off or was digested. Pl. It. led Peritonitis present
Dog 5	Peritoneal graft, oxycel plug used, pressure applied	Alive after 3 days	Rectected for specimen. Slide 7377
Dog 6	Peritoneal graft, oxycel plug, pressure applied	Died 6 days post operati	Peritonitis—leak age under edge 1 case point
Dog 7	Peritoneal graft, oxycel plug, pressure applied	Alive after 33 days	Rectected for specimen Slide 738
Dog 8	Peritoneal graft, oxycel plug, pressure applied	Alive after 36 days	Rectected for specimen Slide 739
Dog 9	Peritoneal graft, oxycel plug, pressure applied	Alive after 35 days	Rectected for specimen Slide 740

plug or the peritoneal fascial graft is the least likely cause for failure. The mechanical failure at the time of sealing is the important factor. Meticulous care during the period of grafting will prevent leakage. The cellulose plug and the peritoneal fascial graft have been shown to be markedly resistant to the autodigestion of gastric juice.

The graft must be held in place for a sufficient time 3 to 5 minutes to allow the adhesive action of the plasma and topical thrombin to take place. The type of pressure clamp used must preferably have a flat surface and it should permit direct vision of the graft at all times during the procedure in order to prevent the eversion or inversion of the edges of the graft. This is the reason for a plastic glass simulated faced clamp as devised by the author. It is also possible to make this clamp in varying sizes to facilitate its use with any size graft desired.

In all the animals the operative wounds healed by primary intention except in dogs 2 and 9. The former was reoperated upon after the fifth day when it was found that the graft had slipped and had become adherent to the gastric serosa 2.5 centimeters from the original graft site. The perforation had temporarily been covered by the liver preventing death.

from peritonitis. This animal had a local wound infection and if permitted to live would have eventually died of peritonitis and wound disruption.

The oxycel plug in addition prevented the graft from blowing off as the result of the production of intragastric pressure from the muscular contractions of the stomach wall and the swallowed air which distended the stomach during contractions. This was seen during the operation when the graft was dropped loosely over the perforation prior to using a plug. It was observed that the graft would balloon up during these contractions over the site of perforation. The plug therefore prevented such displacement of the graft. The segmental contractions that oppose each other at the membrana angularis is another mechanical factor that must be given consideration. It is believed that these opposing contractions may be responsible in some measure, for the cutting through of sutures when attempts are made to close perforations through indurations of the prepyloric or duodenal ulcers.

Experimental dog 9 about the 10th day postoperative, developed an incisional hernia which receded without postoperative intervention and on reoperation 35 days later was found to be only a defect in the abdominal wall itself. The graft had healed completely and was in no way associated with the wound of the abdominal wall. The incisional hernia was in most probability due to poor suture technique in closing the abdomen.

It is with the hope that others may carry on further experimental work along similar lines that this paper is offered. It may possibly develop into a newer and more physiological approach to perforations which are unsuitable for suture closure.

SUMMARY

1. A new experimental method of nonsuture closure of gastric perforations is offered.
2. Nine dogs were used in the experiment. Four survivals of more than 30 days were obtained from the application of an artificial plug and fascial peritoneal graft applied by plasma clot technique.
3. The failures in the experiment are explained on the basis of mechanical defects in the technique of applying the graft.
4. It is hoped that further experimental efforts will be made to develop this technique and apply it to human beings.

ONE STAGE PANCREATODUODENECTOMY

ALEXANDER BRUNSCHWIG M.D. F.A.C.S., Chicago, Illinois

PANCREATODUODENECTOMY has become a recognized procedure for the excision of carcinomas of the ampulla of Vater, head of the pancreas, terminal portion of common bile duct, and neoplasms of the duodenum exclusive of the ampulla but invading the head of the pancreas. Whereas there is agreement on the general principles of the operation, there is still discussion concerning details as to the type of gastrojejunostomy to be performed and the question and manner of reimplantation of the neck of the pancreas into the jejunum. It is generally agreed that choledochojejunostomy with or without cholecystjejunostomy is preferable to cholecystgastrostomy or cholecystjejunostomy because the ligated common duct may open with escape of bile and bile peritonitis.

The incidence of pancreatoduodenectomy is still somewhat limited and for this reason the reporting of relatively small series of such operations with their immediate results is in order. In a previous report (1) in 1943 the author summarized an experience based upon 8 operations; the mortality was 50 per cent. In Whipple's collected series (41 cases) up to April 1941 the operative mortality was 27 per cent. In Orr's collected series from April 1942 to November 1944 (35 cases) it was 26 per cent. This report includes 7 personal unselected and consecutive patients operated upon in which sufficient time has elapsed to permit of the evaluation of immediate results.

CASE REPORTS

CASE 1 N.C. (311069) white male 42 years of age. On October 6, 1943 a partial gastrectomy was performed for what was thought to be a peptic ulcer penetrating into the head of the pancreas. Histologic examination revealed the lesion to be a carcinoma, and sections showed that neoplasm had been left behind on the head of the pancreas. On November 20, 1943 the patient was subjected to one stage pancreatoduodenectomy for excision of

residual carcinoma in the head. There appeared to be no metastases at this time.

A few weeks following discharge from the hospital the patient's general condition began to deteriorate and he died at home March 21, 1944. Necropsy was not obtained.

CASE 2 E.R. (305306) female aged 42 years was admitted to the hospital November 17, 1944, complaining of icterus and pruritus of 6 months duration, upper abdominal pain for 2 days. There had been a loss of 36 pounds in weight during the previous several months.

On November 22, 1944 a one stage pancreatoduodenectomy was performed for a small carcinoma just within the ampulla of Vater. Study of microscopic sections revealed beginning infiltration into the head of the pancreas. There were no lymph node metastases.

Convalescence was uneventful. Since then the patient's condition has been satisfactory and her existence has been normal as to general health and activity. There are two to three bulky light colored stools a day; the appetite is very good. No evidence of recurrences 3 years and 1 month following operation.

CASE 3 C.P. (349868) white male aged 49 years. The patient was admitted to the hospital on January 1, 1945, complaining of a sensation of fullness after meals of 2 weeks' duration and loss of 20 pounds in weight during the previous 3 months. Roentgenographic examination revealed a lesion of the pylorus.

On January 29, 1945 a laparotomy was performed at which time a carcinoma of the pylorus was found infiltrating rather deeply into the head of the pancreas. A one stage pancreatoduodenectomy with cholecystocholedochojejunostomy was performed with implantation of the transected neck of the pancreas into the loop of jejunum brought up for the above anastomosis. Study of the specimen revealed metastases in several nodes.

Convalescence was uneventful and there was healing without fistula.

His condition was satisfactory for 1 year during which time he continued to work. On the occasion of a visit to the out-patient clinic a year after the operation a spherical mass 3 centimeters in diameter was excised from within the lumbar muscles. Histologic examination showed this to be metastatic carcinoma.

In October of 1946 he was readmitted to the hospital because of severe upper abdominal pain (no weight loss) and a deep palpable epigastric mass. A second laparotomy was performed at which time a large mass of recurrent carcinoma in the transverse mesocolon infiltrating the transverse colon and loop of jejunum was excised. He died of shock 3 hours after

From the Department of Surgery, University of Chicago.
This study was aided by the Charles H. and Mary F. F. Worcester Fund of the University of Chicago.

Fig. 1. Photograph of surgical specimen obtained from pancreatoduodenectomy in Case 5. T, Carcinoma; P, head of pancreas (bisected); S, lower stomach; Ch, cholecyst gastrostomy tube (this operation had been performed previously in another institution); L, chain of enlarged lymph nodes from porta hepatis resected along with specimen; Ch, transected and opened lower common duct.

completion of the operation. Necropsy was not obtained.

CASE 4. C.T. (351103) white male aged 7 years was admitted to the hospital February 2, 1945, complaining of 25 pounds weight loss during the previous year, constipation for 4 months and postprandial pains for several months. Roentgenograms revealed an irregular constricting lesion in the third portion of the duodenum with ulceration.

On March 2, 1945, a one stage pancreatoduodenectomy was performed with choledochocholecystojejunostomy and implantation of the transected neck of the pancreas into the loop of jejunum. Pathologic specimen revealed an ulcerating adenocarcinoma of the jejunum infiltrating the head of the pancreas. Regional lymph nodes contained two metastases.

Convalescence was fairly satisfactory. He was discharged from the hospital, but his condition deteriorated at home and he died June 3, 1945, 3 months and 1 week after the operation. Necropsy performed elsewhere revealed carcinomatosis.

Fig. 2. Photograph of surgical specimen removed in Case 7 shows S, lower stomach; entire duodenum and first few centimeters of jejunum; P, head of pancreas; T, transected neck of pancreas; D, carcinoma primary in second segment of duodenum but not associated with the papilla of Vater; L, large metastatic lymph nodes from about head of pancreas and 1, root of transverse mesocolon.

CASE 5. J.M. (378275) white male aged 54 years. In December 1945 the patient exhibited painless jaundice and received an exploratory laparotomy in another city and cholecystgastrostomy was performed. He was admitted to the University of Chicago Clinics March 18, 1946 showing no icterus and in good general condition.

On March 31, 1946, a pancreatoduodenectomy was performed. The cholecystgastrostomy was taken down and the biliary tract drained by choledochocholecystojejunostomy. Study of the specimen (Fig. 1) revealed the carcinoma in the head of the pancreas to be 7 by 5 by 6 centimeters. The resected lymph nodes contained no metastases. Convalescence was uneventful. His condition remained satisfactory until the early fall of 1946 when he began to lose weight and developed palpable masses in the upper abdomen. He died at home in the early part of December, 1946; necropsy was not obtained.

Fig. 3. Diagram of one stage pancreatoduodenectomy without implantation of the transected pancreas into jejunum (*Su & Gyn Obs* 1943, 77: 581)

CASE 6 R.L. (376886) white female aged 49 years. In October 1945, at another institution cholecystectomy was performed for what was interpreted as cholecystitis. 5 weeks later icterus and upper abdominal pain recurred and a second laparotomy was performed at which time a carcinoma of the head of the pancreas was discovered and the abdomen was closed. She was admitted to the University of Chicago Clinics February 27 1946 with mild icterus.

On March 2 1946 a one stage pancreatoduodenectomy was performed. Study of the surgical specimen revealed a small carcinoma in the head of the pancreas just beneath the ampulla of Vater. There was metastasis in one of the two lymph nodes examined.

Convalescence was uneventful, a pancreatic fistula persisted for 6 months and then closed spontaneously.

During the spring, summer and fall of 1946 her condition was satisfactory, appetite was good, there was no gain in weight and there were 2 to 4 bulky light colored stools a day.

In January 1947 two hard rounded masses developed in the abdominal wall beneath the laparotomy scar—obviously recurrences. These were excised and the patient remains well 5 months later.

CASE 7 C.F. white male aged 38 years was admitted complaining of upper abdominal pain, distention, vomiting and 30 pounds loss in weight during previous 6 months.

Röntgenograms revealed a markedly constricting and obstructing lesion in the midportion of the second segment of the duodenum with dilatation of the duodenum above and the stomach.

One stage pancreatoduodenectomy on September 14 1946. The constricting lesion in the second segment of duodenum was obviously a neoplasm. There were markedly enlarged lymph nodes about the head

of the pancreas and in the periaortic region (Fig. 2). The latter were resected separately as a group. Histologic study revealed the primary growth to be a carcinoma. The enlarged nodes showed very pronounced lymphoid hyperplasia with small strands and clumps of metastatic carcinoma cells. Convalescence was uneventful.

June 15 1947 9 months after operation the patient is well, ambulatory and gaining weight. There is a pinpoint pancreatic fistula in the laparotomy scar. He has 2 to 3 light colored bulky stools a day. No special medication. Appetite and strength satisfactory.

RECAPITULATION OF RESULTS

Patient	Pancreatoduodenectomy performed for	Result
Case 1	Carcinoma of pylorus infiltrating head of pancreas	Lived 4 mos. Died of carcinomatosis. No palliation.
Case 2	Carcinoma ampulla of Vater	Living and 11 yrs 6 mos.
Case 3	Carcinoma of pylorus infiltrating head of pancreas	Lived yr 9 mos. Received palliation died with recurrences.
Case 4	Carcinoma of third portion of duodenum infiltrating head of pancreas	Lived little over 3 months—died of recurrences.
Case 5	Carcinoma of head of pancreas	Lived 8 months; died of carcinomatosis; received palliation.
Case 6	Carcinoma of head of pancreas	Living and 6 yr and 3 mos. after operation.
Case 7	Carcinoma of second segment of duodenum, not involving papilla of Vater	Living and well 9 months.

It may be pointed out that of the 7 patients receiving pancreatoduodenectomy in only 3 instances was the procedure carried out for

primary growths of the ampulla or head of the pancreas. In 2 instances the operation was for carcinoma of the most distal portion of the pylorus with invasion of the head of the pancreas and in 2 instances for primary carcinoma in the second and third portions of duodenum respectively not involving the ampulla but invading the head of the pancreas.

The writer up to the present, and with exception of Cases 3 and 4 has followed the technique previously described and illustrated again in Figure 3. There is always a pancreatic fistula that persists for several months following this type of procedure. Reimplantation of the transected neck of the pancreas into jejunum would seem to obviate this drainage and hence would appear to be justifiable on this basis alone not to mention the possibility of returning the pancreatic secretions to the bowel.

For a period following its introduction pancreatoduodenectomy was regarded as a formidable procedure which entails a high mortality. At present the mortality has become appreciably reduced. Of course, this is the usual course of events as illustrated by the histories of partial and total gastrectomy combined abdominoperineal resection etc.

The advances in supportive treatment have permitted such extensions of operative sur-

gery. In regard to cancer necessitating pancreatoduodenectomy the incidence of very prolonged survival will be dependent upon earlier diagnosis of lesions necessitating this operation for this reason awareness of these lesions on the part of physicians will influence the ultimate surgical results.

SUMMARY

Pancreatoduodenectomy has become a recognized procedure to deal with cancer necessitating excision of the lower stomach, the entire duodenum, and the head of the pancreas *en masse*.

A personal series of 7 unselected consecutive pancreatoduodenectomies is reported without surgical mortality.

The relative safety of the operation renders earlier diagnosis of lesions in the ampulla and head of the pancreas all the more imperative in order to achieve an increasing incidence of prolonged survivals.

Addendum.—Since the above report was written, additional pancreatoduodenectomies (one stage) have been performed with surgical mortality. This affords an operative mortality of per cent in a small series of 1 cases. The latter are consecutive and unselected.

ACUTE INJURIES INVOLVING THE LARGE BLOOD VESSELS IN THE NECK

MANUEL E. LICHTENSTEIN M.S., M.D. F.A.C.S., Chicago, Illinois

INJURIES to the large vessels in the neck occur infrequently. The small size of the neck with respect to its exposed surface and the possibility of decreasing this exposed surface by lowering the chin and raising the shoulders makes the prospect of frequent injuries to this part of the body unlikely. Some of those who sustain injuries to the neck involving large vessels succumb immediately from exsanguination strangulation or aspiration of blood into the pulmonary tree. Others die shortly after injury from cerebral changes due to the progress of a thrombus or embolus while still others die from concomitant injuries in the neck.

In addition to the common external and internal carotid arteries there are present in the neck branches of the subclavian artery notably the vertebral artery and the thyrocervical axis with its several branches. Control of bleeding in the neck makes it necessary to have exposed or available in the field access to both the common carotid and subclavian if loss of blood and tissue damage is to be kept at a minimum. Venous bleeding from the internal jugular or subclavian veins may be more difficult to control than arterial bleeding but methods are available to reduce to a minimum blood loss and additional trauma.

This report concerns 6 patients who sustained injuries to the common carotid artery alone or in conjunction with other vascular injuries in the neck and 3 patients who sustained other significant vascular injuries to the neck. The methods employed in the initial management of the cases recorded here are described in the case reports.

CASE 1: Lt W. aged 28 years was wounded by a sniper's bullet at 12 noon January 5, 1944 and was admitted to the hospital 6 hours later. He complained of difficulty in breathing and a rapidly en-

larging mass on the left side of his neck. On examination there was found an entrance wound below the left chin and an exit wound below the left mastoid. Pulsation of the left temporal artery was not present and machinery like sounds were heard on auscultation over the tense mass on the left side of the neck. At 9:00 p.m. under nitrous oxide-oxygen-ether anesthesia administered through an endotracheal tube the left common carotid artery was exposed through an incision along the anterior border of the sternomastoid muscle below the level of the wounds. A tape was passed beneath the artery for provisional control of the flow of blood. The vessels above the level of the wound were similarly exposed and provisional control of the artery and vein was done. There was a free flow of blood between the carotid artery at its bifurcation and the internal jugular vein. There was an extensive hematoma which had dissected downward to the mediastinum and infiltrated the adjacent fascial spaces. The carotid artery at its bifurcation was lacerated for a distance of 1.5 centimeters. The rent extended obliquely from the common carotid below the internal carotid into the external carotid distal to the origin of the superior thyroid artery. The internal jugular vein had two large irregular perforations with loss of substance (Fig. 1).

The opening in the artery was closed with a fine silk suture. The vein was ligated proximally and distally and the intervening portion was removed leaving neither damaged vessel wall nor a distended vessel segment in the wound. Pulsations were noted in the external, internal, and common carotid arteries at the close of the operation. The skin wound was not sutured but the head was turned to the left allowing closure of the incision.

The postoperative course was uneventful. The patient was evacuated to the base hospital on January 18, 1944 with the wound almost healed. There were no mental or physical disabilities. After study of his condition with special reference to mental or central nervous system changes over a period of several weeks he was discharged to full duty as an infantry officer.

The location of the injury in the artery was such that the control of bleeding by ligature would have required ligations of the common external and internal carotid arteries and the superior thyroid artery. That suture of large rents is possible is demonstrated by this case. Anticoagulants were not used but it is likely

that their use is desirable to preclude the possibility of thrombosis in large vessels. Decompression of the fascial spaces of the neck with evacuation of the hematoma is desirable because of the danger of infection in a contaminated wound containing stagnant blood. There was no clinical evidence of infection in the wound at anytime and in the light of subsequent experience provisional closure of the wound may be desirable. However it is remarkable that positioning the head properly

permits closure of the wound without suture and healing takes place with a fine scar.

CASE 2. Pvt. S. aged 20 years, sustained a bullet wound of face, jaw and neck at 9:35 a.m. January 7, 1944 and was admitted to the hospital at 2:15 p.m. of the same day. He was cyanotic and dyspneic from tracheal obstruction and tracheotomy was done at 2:30 p.m. A bullet penetrated over the left malar bone causing a compound comminuted fracture of the left mandible, compound fracture of the hyoid bone and laceration of the trachea. The bullet lodged in the right supraclavicular fossa 1 front of the 7th

Fig. 3a.

Fig. 3. a. Drawing showing wounds and treatment in Case 3 b. Note displacement of trachea to side opposite to location of vascular lesion. Injury to common carotid artery, internal jugular vein, and inferior thyroid artery.

Fig. 3b.

transverse cervical process. At 12 30 a. m. January 8 1944 under ether anesthesia administered through the tracheotomy tube, the wound over the left malar bone was debrided. The deep structures on the right side of the neck were exposed and it was found that the bullet had penetrated the lumen of the right common carotid artery. Removal of the bullet was followed by a free flow of blood. Control of bleeding was effected by the use of a 'stick sponge' placed behind the clavicle to compress the proximal portion of the carotid artery. The defect in the artery was extensive. To control bleeding the wound in the artery was closed by suture starting distally and proceeding proximally until the lumen was occluded. The damaged segment was excised after proximal and distal ligations.

The jaws were wired on January 9 and the tracheotomy tube was removed on January 14. The patient was evacuated to the base hospital on January 18. There were no mental or physical changes related to ligation of the carotid artery. When seen 4 weeks later he was making satisfactory progress awaiting healing of the fractured mandible.

The location of the bullet low in the neck with active bleeding upon its removal suggested several more extensive procedures for

control of hemorrhage at this level. The method used—obliterative closure of the lumen of the vessel at the level of the damaged segment by the placement of a continuous suture starting distally and proceeding proximally until all bleeding was controlled made possible proximal and distal ligations in a dry wound. Cutting the clavicle resection of the clavicle in part or dislocation of the sternoclavicular joint for a more liberal exposure of this part of the vessel may be necessary in similar instances. However the method made use of in this case was adequate for the purpose.

CASE 3. Pvt. N. aged 18 years sustained a shell fragment wound of the neck at 6 30 p. m. January 11 1944. He complained of difficulty in swallowing was dyspneic and had considerable swelling of the neck. There was a small wound of entrance on the right side at the level of the cricoid cartilage. All structures in the pharynx were hemorrhagic and edematous. An x-ray study showed considerable deviation of the trachea to the right with a foreign body lodged

Fig. 4a.

Fig. 4b.

Fig. 4. a, Wounds and treatment in Case 4. b, Not displacement of trachea. Injury to common carotid artery.

in the left supraclavicular fossa. At 6:00 a.m. January 12 under nitrous oxide-oxygen-ether anesthesia administered through an endotracheal tube (after preliminary cannulization of the pharynx and larynx), an incision was made along the anterior border of the left sternomastoid muscle. The common carotid artery was provisionally controlled proximal to the site of the injury. An arteriovenous communication was present. A large accumulation of blood was evacuated from the adjacent spaces. In spite of control of the common carotid artery and internal jugular vein a brisk flow of blood filled the wound. Pressure over the subclavian controlled this bleeding. It was found that the source of this bleeding was the completely severed inferior thyroid artery. The proximal and distal ends of this vessel were ligated. The common carotid artery was ligated proximal and distal to the injured zone and the intervening segment was removed. The internal jugular vein was similarly excised following high and low ligations. The neck wound was not sutured but closed by turning the head to the left. Recovery was uneventful and on January 21, 1944 he was vacated to the base hospital. There were no mental changes and no central or peripheral nervous system alterations were noted. On February 1, 1944 complete closure of the neck

wound was done under nitrous-oxide-oxygen anesthesia. Postoperatively he had a right hemiplegia. During the following 4 weeks he made a gradual recovery and when last seen at that time was up and about but wrist drop was still present.

Operations under anesthesia which may be associated with anoxemia should not be undertaken for some time after a carotid ligation. A period of 6 weeks to 2 months would not be too long a period. The Matas test is desirable in determining the competency of cerebral circulation.

Secondary closures of neck wounds may be avoided by instituting primary closure or by permitting wound closure without suture by positioning of the head and proper bandaging. Case 1 related previously had no secondary closure for a similar wound but the scar was finer and smoother than that in Case 3.

It may appear ambiguous to caution against anesthesia which may result in anoxia when

Fig. 5a.

Fig. 5. a. Wounds and treatment in Case 5 b. Zipper fragments within wound. Injury to common carotid, superior and inferior thyroid arteries, external and anterior jugular vein, thyroid gland, perforation of the cricoid.

Fig. 5b.

the immediate operation was done under nitrous oxide-oxygen-ether anesthesia. It must be emphasized that in these patients a special effort is made to avoid anoxia and an adequate amount of oxygen is administered from the very beginning.

It is also possible that an embolus liberated from a thrombus at the site of ligation of the distal end of the common carotid artery was responsible for the hemiplegia although 3 weeks had elapsed since surgery was done. Whatever the reason may be this patient illustrates a hazard associated with damage to a carotid vessel. The need for the prevention of anoxia during anesthesia and for some time thereafter and a technique that will prevent thrombosis with its hazard of embolism are worthy of emphasis.

CASE 4. Pvt F. aged 19 years, sustained a shell fragment wound of the left side of the neck at 2:00

p.m. February 19, 1944, and was admitted to the hospital at 6:30 p.m. of the same day. He was dyspneic and had a pulsating swelling on the right side of the neck. The wound of entrance was small, located over the sternomastoid muscle at the level of the thyroid cartilage. An x-ray study showed deviation of the trachea to the left with the foreign body lodged in the right side of the neck (Fig. 4). Because of the development of extreme difficulty in breathing a rapid endotracheal intubation was done under light anesthesia. Following this nitrous oxide-oxygen-ether anesthesia was continued successfully and exploration of the right side of the neck was done. After provisional control of the common carotid artery proximal and distal to the site of injury a hematoma was evacuated and two irregular perforations of the arterial wall were noted. The extent of damage did not warrant suture of the defects since restoration of the lumen was not possible. The artery was ligated proximally and distally and the segment involved was excised. The wound was loosely closed. Recovery was uneventful and on March 10, 1944 the patient was evacuated to the base hospital. He showed no mental changes and there were no central or peripheral nervous system defects noted.

Fig. 6 a, Wounds and treatment in Case 6 b, Extreme displacement of trachea. Injury to common carotid and vertebral artery

There was no injury to the jugular vein in this case. No effort was made to isolate or ligate this structure. The matter of concomitant vein ligation when a large artery is severed as is frequently practiced in arterial wounds of the extremities needs further inquiry. In the immediate postoperative period for almost three weeks the patient showed no changes that would suggest a better result following vein ligation.

CASE 5. Lt R, aged 23 years, was injured at 11:00 a. m. February 28, 1944, when high explosive shell fragments penetrated his neck. He was taken to an advanced dressing station (Brit.) where it was found that he was pulseless, moribund, cyanotic, and cold. He was given immediately 1500 cubic centimeters of blood and $\frac{3}{4}$ grain morphine (?) intravenously. Through the open wound hemorrhage was controlled by ligatures and sutures. He responded well and at 1:30 p. m. his pulse was 80 and he appeared to be in good condition except for some bloody expectoration. He was evacuated and arrived at the hospital at 4:30 p. m. February 28, 1944. On admission his condition was satisfactory: temperature 38.6, pulse 80, respiration 20, blood pressure 120/82. There was a swelling on the right side of the neck and in the right

suprascapular fossa. In the center of the anterior surface of the neck there was a large defect in the skin measuring approximately 2 inches in diameter. Much blood oozed from the wound and no pulse was obtained in the right temporal artery. An x-ray study showed many small and one large metallic fragments in the soft tissues of the neck. At 6:30 p. m. under nitrous oxide-oxygen-ether anesthesia he was intubated with some difficulty because of considerable edema about the glottis. Wound excision was done. Zipper fragments, cloth and dirt were removed and a large portion of the right lobe of the thyroid gland was resected. The severed external and anterior jugular veins were ligated, the superior and inferior thyroid arteries were ligated, and the right common carotid artery was ligated proximal and distal to a large irregular opening in its wall. The right suprascapular fossa was exposed, a hematoma evacuated, and a small bleeding vessel was ligated.

During the operative procedure the blood pressure readings varied considerably. At one time the systolic pressure was 180, diastolic 110. Following surgery his blood pressure was 120/50, pulse 106, and respiration, 22. He was given 500 cubic centimeters of blood during the course of surgery. He did not awaken until 5:00 p. m. of the following day. During this period his pulse and respiration did not vary much but his blood pressure slowly rose to 140/60. At this time it was noted that there was a left-sided

Fig. 7a.

Fig. 7. a Wounds and treatment in Case 7. b, Injury to transverse cervical artery

Fig. 7b.

hemiplegia. Vomiting occurred at noon February 29 and the patient showed marked drowsiness and difficulty in swallowing. At 4:00 p.m. he became comatose and showed marked spasm of both sides of the body. During the next 4 hours his blood pressure ranged between 185 and 210 systolic and between 0 and 90 diastolic. He never regained consciousness from this point on. A lumbar puncture gave a clear colorless fluid containing 2 white blood cells per cubic millimeter. The spinal pressure was 310 millimeters. Following the puncture there was a slight drop in the pulse and blood pressure but at midnight February 29 the pulse rose to 136, respiration, 24, blood pressure 152/90. He failed rapidly and expired at 1:00 a.m. March 1, 1944.

Autopsy (extract of report by Dr. Leo Kaplan)

There is found an extensive hemorrhage extending along all the fascial planes on the right side of the neck posteriorly to include the muscles of the posterior triangle of the neck superiorly to the base of the skull along the right sternomastoid and retropharyngeal space and inferiorly behind the esophagus into the entire posterior mediastinum to the diaphragm. There is no local accumulation of blood and there is no evidence of any recent bleeding. A small segment of the posterior aspect of the right lobe of the thyroid is found containing multiple sutures and separated from the isthmus of the thyroid by a defect. The superior and inferior thyroid arteries have been ligated. Two distinct sutures are found about the

right common carotid artery in the inferior aspect of the neck. There is a 6.0 centimeter defect between this point and that of the distal segment of the same artery where a silk ligature is found placed about the vessel. The vessel has retracted into the carotid sheath.

Within the proximal segment of the right common carotid artery is found a propagating thrombus which extends inferiorly for a distance of 4.5 centimeters. Within the distal end of this vessel is an other small nonadherent thrombus which measures 1.0 centimeter in length.

Dissection of the larynx shows a small perforation with margins that fall against each other. This wound passes through the substance of the cricoid cartilage in its right half and opens into the larynx. The thyroïd cartilage above this point is linearly fractured. The submucosal tissues about this fracture and perforation site are edematous and filled with organizing hemorrhages as far superiorly as the true vocal chord. The mucosa surrounding the puncture site is coated by a fibrinous membrane.

The dural alnuses are everywhere patent. The dura especially over the convexities is slightly adherent to the pia-arachnoid by very fine white fibrous strands which separate with slight difficulty. There is no evidence of any subarachnoid bleeding. Both cerebral hemispheres are swollen and exhibit gyral flattening but the left hemisphere is distinctly larger than the right. Dissection of the great vessels

Fig. 7a

Fig. 8b

Fig. 8. Wounds and treatment in Case 8. b. Large foreign body with slight tracheal displacement. Injury to superior thyroid artery, vein, extensive injury to internal jugular vein

of the brain shows an intact circle of Willis, internal carotid artery basilar and vertebral arteries. A dissection of the right middle cerebral artery reveals a complete thrombosis beginning at a point 3.0 centimeters from its point of entrance to the Sylvian fissure. From here on the branches of the middle cerebral exhibit a staghorn type of thrombosis. There is an extensive softening of the right cerebral hemisphere most marked in its midportion and especially in the region of the basal ganglia. The right lateral ventricle is somewhat narrowed as compared with the left. The left cerebral hemisphere is edematous and slightly hyperemic. Serial section of the midbrain, pons and medulla show the former two to be the seat of extensive discrete and focal hemorrhages and areas of softening which are most prominent on the left side and in the periaqueductal region. The left superior cerebellar artery in some of its smaller branches which extend into the brachium pontis are thrombosed and encased in a small fusiform hematoma (etiology?). The medulla and the cerebellar hemispheres are edematous.

This patient sustained a severe injury to the neck involving many small vessels in addition to the right common carotid artery. Embol-

ism and thrombosis played a rôle in the changes which were fatal. The alterations in blood pressure and cerebral edema developing during surgery may indicate that manipulation soon after the first and second efforts in controlling hemorrhage may have been a factor in liberating emboli. The case study emphasizes the importance of the development of thrombi in traumatized vessels more especially when the blood flow through the vessel is impaired by a prolonged drop in blood pressure. The blood pressure phenomenon which developed at the time of surgery would indicate that cerebral changes of a serious nature had already occurred.

In the immediate care at the casualty station the value of a large amount of blood administered to replace a blood loss is illustrated. An important point for discussion concerns the advisability of occluding the wound until complete initial surgery can be undertaken.

Fig. 9. Wound and treatment in Case 9

The grasping of bleeding vessels in a dirty wound with the placing of ligature and sutures may be a predisposing factor to thrombosis and early embolism. A desperate situation frequently requires what appear to be desperate means to preserve life. Since such desperate action may in itself preclude ultimate recovery it would appear desirable to consider all of the possibilities to control bleeding until the patient can be transported to a hospital where necessary initial surgery may be undertaken. Packing as a temporary measure may be more desirable than sutures and ligatures in a contaminated field.

CASE 6. B. M. aged 10 years, found a fountain pen booby trap near Anzio. On manipulation it exploded and a metal fragment penetrated the right side of his neck. He was taken to an aid station at 6:30 p. m. June 7, 1944 and evacuated to the hospital at 8:00 p. m. He was dyspneic, had a small wound in the midline at the level of the cricoid cartilage and a swelling on the right side of the neck. An x-ray study showed marked deviation of the trachea to the left with a foreign body at the level of the 7th cervical vertebra. There was considerable oozing of blood from the external wound. At 10:00 p. m. under ether anesthesia administered through an endotracheal tube an incision was made along the anterior border of the right sternomastoid muscle. The common carotid artery was exposed and provisionally controlled. This, however did not control hemorrhage from the wound but pressure over the subclavian deep in the wound permitted exploration in a dry field. It was found that the single metal fragment had severed the right vertebral artery at a site proximal to its entrance into the vertebral foramen and in addition lacerated irregularly the right common carotid artery. The nature and extent of the laceration in the carotid did not warrant suture. Ligations of both vessels proximal and distal to the site of injury were done. The damaged portion of the carotid was excised. The wound was loosely closed. He was given 500 cubic centimeters of blood during surgery. The postoperative course was uneventful during the 5 days of observation. There were no

mental cerebral, or peripheral nervous system changes. He was out of bed on the fourth day, talked with his parents and ate his meals without difficulty. Because of the tactical situation he was evacuated to the rear and observation beyond the 5th postoperative day was not possible.

It would be desirable to have had more detailed follow up data in this case. The injury to two of the four vessels which carry blood to the brain did not appear to have had an unfavorable effect on this youngster during the time of observation. The internal jugular vein was not injured and was not occluded.

CASE 7. Sgt. J. aged 25 was injured October 13, 1944 7:30 p. m. by a shell fragment which penetrated the right side of the neck posteriorly and lodged in the right supraclavicular fossa. He was admitted to the hospital at 2:10 a. m. October 14. Swelling and tenderness were present on the right side of the neck with oozing of blood from the irregular wound over the right trapezius muscle. A supraclavicular incision exposed the tract of the missile. The foreign body was lodged against the damaged transverse cervical artery which had an aneurysmal dilatation at the site where it passes between the cords of the brachial plexus (Fig. 7). All bleeding vessels were ligated, damaged tissue was removed and the wound was left open. No unusual symptoms were present or developed in the immediate postoperative period and he was evacuated to the base hospital on October 19, 1944.

This type of trauma illustrates vessel injury without penetration perforation or severance. It is likely that many injuries similar to this occur unassociated with immediate hemorrhage. Some are followed by hemorrhage when sloughing or perforation of the damaged vessel occurs. Others develop aneurysms which require ablation at a later day.

CASE 8. Lt. M. Italian soldier aged 25 years, sustained shell fragment wounds of his face, neck and shoulders at noon October 28, 1944, and was admitted to the hospital at 7:45 p. m. of the same day.

On admission he was in a state of shock and blood pressure when obtainable was 80/20. He improved following 500 cubic centimeters of whole blood. There was a small laceration of the face, a few wounds of the left shoulder and a lacerating wound of the left side of the neck 2 inches long at the level of the larynx. A large irregular foreign body was inclosed in the left supraclavicular fossa at the site of a welling. Under nitrous oxide-oxygen-ether anesthesia the left side of the neck was explored through an incision along the anterior border of the sternomastoid muscle. The superior thyroid artery and vein were severed and a defect was present in the superior pole of the left lobe of the thyroid. The internal jugular vein was extensively lacerated over a considerable distance. Hemorrhage was controlled by the positioning of stick sponges at sites proximal and distal to the bleeding vessel. All bleeding points were ligated. The internal jugular vein was ligated high and low and all damaged tissue with the foreign body was removed from the wound. Loose closure of the wound was done. No unusual changes developed and he was evacuated on November 8, 1944 in good condition.

Bleeding from a large vein is at times more troublesome than bleeding from a large artery. Extreme care must be exercised to prevent tearing of the vessel when efforts are made to control bleeding. Gentle compression over the wound and careful dissection with instruments that are smooth aid considerably in placing ligatures properly.

CASE 9. Pvt. F. aged 29 years was injured July 8, 1944 by a shell fragment which perforated the neck. The entrance wound was on the left side at the level of the chin and the exit was on the same side below the mastoid process. There was some swelling in the anterior triangle of the neck but no tenderness and little pain. Some difficulty in breathing was experienced. Examination showed the larynx, glottis, left tonsil, and posterior pharynx edematous. Intratracheal intubation was accomplished under nitrous oxide-oxygen-ether anesthesia. Through an incision parallel to and below the inferior margin of the mandible the tract of the missile was exposed. The internal jugular vein was completely transected, were the venous tributaries from the submaxillary gland. The missile passed posterior to the carotid artery without injury to this vessel. All bleeding points were ligated, but control of bleeding from the cephalic end of the jugular vein was difficult because of retraction of the vessel. By the use of a silk suture applied to the bleeding site with fixation in the adjacent sternomastoid muscle it was possible to control the bleeding without damage to adjacent structures. Recovery was uneventful and the patient was evacuated to the base hospital on July 17, 1944.

In this particular case as well as in several others where the source of the bleeding is a

large vein it is of the utmost importance to refrain from using forceps to control bleeding points. Veins have thin walls, tear easily and have a tendency to permit blood to well up into the wound. The use of stick sponges to block out the zone of bleeding with a systematic approach to the site of bleeding for careful isolation of the vessel before ligation or suture is done are most helpful in the control of hemorrhage.

In some cases it is found that ligation of the internal jugular vein permits a sac filled with blood extending from the ligated cardiac end to the next distal tributary. It is desirable to ligate the vein adjacent to the nearest tributary to prevent this blind sac from existing. In wounds that are contaminated from penetrating and perforating foreign bodies, the dangers of thrombosis, phlebitis, and sepsis warrant the removal of all stagnant accumulations of blood.

RÉSUMÉ

This series of vascular injuries in the neck does not represent all the patients with vascular injuries admitted to this hospital. However the cases not recorded here represent for the most part injuries to the external anterior and internal jugular veins and such smaller vessels which were available in the wound without extensive loss of blood or hematoma formation. The one death in this series is recorded in some detail (Case 5).

From a review of these cases it appears that the following general comments are warranted:

1. Vascular injuries in the neck are not common but are serious and may be fatal.
2. Blood for replacement of that lost either before or during surgery must be available at hand and ready for use.
3. Anesthesia must afford a high oxygen intake. A competent anesthetist familiar with the necessary techniques and conscious of the special needs of the patient with this type of injury is a valuable asset. Local anesthesia for an elective procedure may be desirable to avoid anoxia that may be associated with general anesthesia. However a recently injured patient in full knowledge of his injury especially when some dyspnea is present is very anxious to be put to sleep. In addition

where the exposed wound is obscured by blood and damaged tissue complete anesthesia with novocain may not be possible. A seriously wounded patient should not be subjected to physical or mental pain with incomplete anesthesia. Also a struggling patient cannot co-operate and a bleeding neck wound requires a deliberate and careful approach to prevent adding to the damage done by the missile. It is noteworthy that almost all of the patients with neck wounds done at the hospital were awake immediately after surgery was completed following nitrous oxide-oxygen ether anesthesia which was administered by a competent anesthetist using the endotracheal technique.

4 Ligation of vessels should be done at sites free from trauma and adjacent to branches or tributaries to prevent thrombosis in the 'blind segment'.

5 It is noteworthy that in those patients who sustained wounds of the neck involving blood vessels, injury to the larynx trachea, pharynx or esophagus or both were rare (Case 5—trachea and larynx, Case 2—trachea). In another series of 10 patients who sustained injuries involving the larynx pharynx or esophagus or both there were no large vessel injuries.

6 Ligation of the carotid artery soon after trauma is usually not followed by mental cerebral or peripheral changes in the age group noted in this series. It is obvious that occlusion of the common carotid or the internal carotid results in a marked diminution in the blood supply to the brain. It is difficult to explain why in some patients this brain anoxia is temporary and not destructive of the functions of the brain while in others changes

of great severity rapidly ensue. Many theories have been offered but there is probably no one which will satisfactorily explain the phenomenon in every case.

The dangers associated with ligation of this important vessel warrant the use of reconstructive methods and anticoagulants.

7 Venous bleeding in the neck is best controlled by careful isolation of the damaged vessel ligation of the bleeding point or when necessary suture of the bleeding site.

8 While the prevention and control of infection was based on the surgical principle of decompression of fascial spaces by incision all of the patients were given sulfadiazine or penicillin. The former was given routinely in 5 gram doses daily for 5 to 7 days to patients admitted prior to May 1944. The latter was given in 25 000 unit doses intramuscularly every 3 hours for 5 days subsequent to May 1944. The rôle these agents played in the prevention or the control of infection in these patients was the same as in other patients with wounds elsewhere on the body.

SUMMARY

In patients requiring immediate control of bleeding from a large vessel in the neck, adequate blood replacement before and during surgery is necessary. An anesthetic offering a high oxygen content with free passage of oxygen into the lungs is imperative. Thoughtful planning for provisional control of bleeding from an injured vessel will avoid unnecessary loss of blood. Excision of damaged tissue will prevent to some degree thrombosis and embolism. Cleansing of the contaminated wound and the use of penicillin helps to avoid infection and its sequels.

IMPROVEMENT IN ABDOMINAL HYSTERECTOMY MORTALITY

ROGER S. SIDDALL, M.D. F.A.C.S., and HAROLD C. MACK, M.D., F.A.C.S.,
Detroit, Michigan

IN a previous report from Harper Hospital¹ we published the death rate for abdominal hysterectomy (excluding pelvic malignancy hysterectomy after cesarean section and for obstetrical emergencies such as ruptured uterus) during the 5 years 1928-1932 inclusive. Mortality rates for total and subtotal hysterectomy were respectively 6.4 and 2.6 per cent. In view of the changes in pelvic surgery and the general improvement of surgical mortality in all fields in recent years, we undertook a similar study of results for the 5 years 1941 to 1945. Comparing the mortality rates, and excluding as before, all hysterectomies for pelvic malignancy and obstetrical emergencies a striking difference was at once apparent.

	1928-1932			1941-1945		
	Cases	Deaths	%	Cases	Deaths	%
Subtotal hysterectomies	14	30	6	14	7	50
Total hysterectomies	117	5	6	117	6	64
	(17.5)			(26.7)		
All cases	131	35	2	131	13	22

The dramatic improvements for all groups shown in this comparison of results, as well as the near equality of mortality rates for total and subtotal hysterectomies in the latter 5 years, prompted us to undertake a study of all abdominal hysterectomies performed at Harper Hospital for the entire period 1928 to 1945 inclusive. Thus there would be not only a comparison of two 5 year series from different periods, but also a record of the transition years between. It was thought that such investigation would better determine the factors responsible for the improved results now obtained and could lead to valuable sugges-

tions for further betterment. In order to present the complete picture, we decided to include consideration of *all* abdominal hysterectomies i.e. those done for pelvic malignancy and obstetrical complications as well as the benign conditions. Actually however this changed the mortality figures only slightly and simplified calculations. This inclusion moreover now permits comparison of results with series from other institutions.

ABDOMINAL HYSTERECTOMIES 1928-1945

The complete series comprises 6692 abdominal hysterectomies of which 2,050 (30.7 per cent) were total hysterectomies. These operations were performed by approximately 100 gynecologists, surgeons, occasional operators and residents in training representing varying degrees of skill and experience.² The women operated upon were, in the vast majority private patients. The operations contained examples of virtually every known technical variation in the performance of abdominal hysterectomy. The differences in technique, however, were not sufficiently clear-cut to permit classification and comparison of methods during this period.

Incidence of hysterectomies (Fig. 1) shows the numbers of abdominal hysterectomies performed each year from 1928 to 1945 as well as the numbers of complete and subtotal operations compared to the yearly totals. The increasing employment of hysterectomy during the 18 year span in spite of no increase in hospital beds or appreciable additions to the staff suggests a growing tendency to substitute ab-

In our first publication the importance of experience of the operator as judged by the numbers of hysterectomies performed, was clearly demonstrated. However, since the last 5 years of the series fell within the 18 years, the consequent absence of many of the staff of all age groups for variable periods, any estimate on the basis of operations performed would obviously be of questionable value, particularly when compared to the original series. Consequently this method of calculation was not attempted in the present study.

From Harper Hospital and Wayne University College of Medicine.
Presented at the November, 1946 meeting of the Michigan Society of Obstetricians and Gynecologists.
R. S. Siddall and H. C. Mack, Surg., Gynecol. & Obst., 422, 66, 62.

Cases

Fig. 1. Incidence of hysterectomies. White columns, all abdominal hysterectomies; crosshatched areas, supravaginal hysterectomies; black areas, panhysterectomies.

dominal hysterectomy for other gynecologic procedures.

In addition to the increased election of abdominal hysterectomy there is evident also a steady growth in selection of the total operation. Whereas, in 1928-1932 only 20.7 per cent of all abdominal hysterectomies were of the complete variety, the 5 years 1941-1945 showed that this proportion had doubled (41 per cent). It is noteworthy that this increase in the choice of panhysterectomy occurred in spite of the virtual abandonment of radical hysterectomy for carcinoma of the cervix in favor of radium and roentgen ray therapy in recent years. In view of this curtailment the selection of the total operation has obviously been extended for other indications.

Mortality. Among the 6,692 abdominal hysterectomies there were 119 deaths. An analysis of the mortality for the various groups as given in Table I shows a remarkable decrease in the death rate from 3.7 per cent in the years 1928-1932 down to 0.78 per cent in the 1941-1945 period, with the intervening years 1933-1940 at 1.65 per cent. Expressed differently, the risk in each of the last two periods was less than one-half that of the previous one. Moreover, this dramatic improvement

has occurred with both the total and subtotal operations.

TABLE I—COMPARISON OF MORTALITIES FOR THE THREE PERIODS AND FOR SUPRAVAGINAL AND PANHYSTERECTOMY

	1928-1932			1933-1940			1941-1945		
	Cases	Deaths	Per cent	Cases	Deaths	Per cent	Cases	Deaths	Per cent
All cases	3,456	14	3.7	785	46	6.3	2,115	9	0.78
Subtotal hysterectomy	55	2	3.6	203	23	6.2	447	1	0.76
Total hysterectomy	90	2	2.2	720	1	7.1	804	8	0.82

The most striking feature of Table I is the improvement in panhysterectomy mortality. While the risk of the subtotal operation has been reduced very substantially down to a figure between one third and one-fourth the total hysterectomy mortality in the last group was only one-ninth of that of the first 5 years. This means that total hysterectomy, which was more than two and one half times as dangerous as supravaginal in the first 5 years, reached near equality in the last two periods. The mortality percentage for the two types of operation by years is shown in Figure 1. It is

noteworthy that in the years 1941 and 1942 there were 352 consecutive panhysterectomies without fatality.

The approach to pancy in mortality of the two types of hysterectomy would seem to in validate the conclusion in our first report that, in view of the greater risk at that time total hysterectomy was not justified *routinely* as a prophylactic procedure against carcinoma of the cervix. Certainly the tremendous improvement in results now permits a very wel come extension in the use of the complete operation. Nevertheless there are several reasons to believe that the mortality figures of the two operations are not altogether com parable and consequently do not give the true picture regarding the relative operative dangers. This is evident from the fact that in accord with prudent surgical judgment the poorer risk patients tend to have the less for midable operation except in the rather few instances where panhysterectomy is absolutely imperative. It is interesting to note that this selection of poor risk patients for supravaginal hysterectomy seemed to apply to instances of malignancy as well as to benign conditions. For example, in 1941-1945 the two patients with malignancy who died after panhysterec tomy were without question in excellent con dition in one case and a fairly good risk in the other. In contrast, of the three fatalities after subtotal hysterectomy during this same per iod one was 74 years old with marked anemia renal insufficiency and peritonitis another had marked anemia, evidence of intestinal obstruction due to widespread peritoneal im plants from ovarian carcinoma, and weighed 260 pounds and the third died of peritonitis following perforation of the bowel while the pelvic organs were being freed of adhesions. This third case is an example of the fact that it is also fairly common practice to change preoperative plans for total hysterectomy to subtotal removal because of operative acci dents, unexpected technical difficulties or the necessity for speedy conclusion of the operation. Obviously in these circumstances an in advisable persistence in carrying out the more extensive operation would without fail sub stantially increase the mortality rate. More prudent selection of cases must have played

an important part in the reduced mortality of panhysterectomy in our later series.

Causes of death. To determine the causes of death in the 119 fatalities in this series was probably the most difficult portion of the study. Incomplete records as well as inade quate clinical and laboratory data were promi nent shortcomings, especially in the earlier cases. In the absence of adequate blood studies and blood pressure records, it was fre quently necessary to glean the criteria for the probable diagnosis from data given in the nursing notes often more informative than progress notes of the attending and resident staff. Where ample information was avail able the data were at times contradictory and often there were confusing multiple contribu tory causes. Even in a few cases with com plete postmortem examination considerable doubt as to the primary cause of death existed. Table II summarizes our best estimate of the causes of death.

TABLE II—CAUSES OF DEATH

	Entire series		1940-1943		1944-1946		1947-1948	
	N	Per cent	No	Per cent	No	Per cent	No	Per cent
All causes			54		46		30	
Peritonitis (infection)	64	53	23	64	23	50	6	21
Hemorrhage (shock, cardiac)	7	5	8	2	14	30	5	16
Embolus	14		9	7				11
Pneumonia		6			5			5
Aplasia	3							
Diabetic coma								
Uremia								
Meningitis								
Associated carcinoma		18		2	2		1	16

From Table II it is immediately apparent that infection, hemorrhage with shock and cardiac failure and embolus play the principal rôles in the entire series. The interchange of the last cause with pneumonia in the second period is probably only incidental to the small numbers involved. In assigning the principal causes of death after review of the case records, the combination of anemia (preoperative or resulting from operative blood loss) and in-

fection (peritonitis ileus) in the same patient frequently made it difficult for us to determine which factor was primary. Similarly many instances of probable surgical shock with early fatal outcome had originally been catalogued as myocardial failure. Acknowledging valid objections to including deaths from shock and hemorrhage with those of cardiac failure we have continued this grouping (as in our first publication) to facilitate comparison between the groups and also because of the difficulties of differentiating between these conditions through lack of adequate clinical and laboratory data. Regardless of the acknowledged shortcomings of such *ex post facto* deductions it is possible to ascertain certain trends in the preoperative and postoperative care of these cases which may explain some of the improvements attained.

In Table III are given the causes of death with subtotal and total hysterectomy for the 5 year periods 1928-1932 and 1941-1945. The figures demonstrate marked improvement for both types of operation. They also show again that in spite of this improvement the same causes of death are important now as before.

ANALYSIS OF CAUSES OF DEATH

Gratifying as it is to report the great improvement in the mortality results for hysterectomy at Harper Hospital the most important function of this study is an inquiry into measures for further betterment. Most promising for that purpose appeared to be

further analysis of the major causes of death to discover improvements in treatment which could have been responsible for the lowered mortality of the later periods. It was hoped that in this way leads to further improvement might become evident.

Infection As is shown in Table II postoperative peritonitis was numerically and proportionately the greatest contributing factor to mortality in the entire series and in each of the three time intervals. Of all patients subjected to hysterectomy during the 18 year period 0.95 per cent died as a consequence of infection. It was the cause of death in 0.75 per cent of supravaginal and 1.4 per cent of panhysterectomy operations. A dramatic contrast however is evident when we calculate the incidence of fatal peritonitis in the three periods represented in this series in 1928-1932 it was 2.4 per cent in 1933-1940 it declined to 0.82 per cent and in 1941-1945 it reached the low figure of only 0.24 per cent. In other words the risk of death from peritonitis in the last 5 year span was only one tenth that of the first series. A similar decline was noted when the death rate for peritonitis was calculated according to type of operation per rates per cent were 1.5, 0.58 and 0.34 respectively for the three time groupings and for 0.1 per cent respectively.

In attempting to explain this striking lowering of the death rate from infection several potential factors were considered (1) incidence of malignancy (2) incidence of acute salpingitis (3) preoperative and postoperative treatment of anemia (4) chemotherapy.

Malignancy The frequent sequel to pelvic surgery for malignancy namely peritonitis has long been recognized. The fact however that death from infection has diminished despite a proportional increase in deaths associated with malignancy (Table II) would make it seem likely that some factor other than a lowered incidence of malignancy in recent years accounts for the declining death rate from infection.

Salpingitis A partial explanation for some lowering of the death rate from infection is found in the declining frequency of operations

for 'pus tubes.' Among the 64 peritonitis (infection) deaths in this series, there were 9 with pathological evidence of acute or sub-acute salpingitis. It seems significant that 7 of these deaths occurred in the 5 years 1928-1932 2 were recorded in 1933 1940 and none such were noted in 1941 1945. These figures suggest that selection of patients with respect to preoperative pelvic infection contributed to a lowering in the infection death rate. The fact however that infection was fatal only one-sixth as often in 1941 1945 as in 1928-1932 makes it likely that other factors were also responsible.

Preoperative and postoperative treatment of anemia. In an attempt to determine the effect of preoperative and postoperative treatment of blood loss upon the mortality of hysterectomy we have investigated the incidence of blood transfusions among all patients subjected to hysterectomy. We have also calculated the frequency of transfusion among those who died following hysterectomy on the assumption that this might give a clue as to the energy with which these serious cases were treated. Grouped in 2 year periods these relationships are shown in Table IV.

TABLE IV—RELATIONSHIPS OF HYSTERECTOMY MORTALITY TO FREQUENCY OF PREOPERATIVE AND POSTOPERATIVE BLOOD TRANSFUSIONS

Years	No.	Deaths		Infection deaths		Hysterectomy transfused		Hysterectomy deaths transfused	
		No	Per cent	No	Per cent	N	Per cent	No	Per cent
1923-29	637	30	7	73	3.6	7			
1930-31	330	13	3	6	6	3	6	3	20.6
1932-33	303		6	6		15		5	41.4
1934-35	677	3		6	73		6		0
1936-37	779			5	4.1	47	6		
1938-39	603	3	8	8	3	67	9.6	6	66
1940-41	681	8			43		1.5		16
1942-43	960			6	30	30.7	30		37
1944-45	971	9	9		10	most tabulated			33.3

It seems evident from Table IV that the decline in general mortality and in death from infection bears a relationship to or at least

parallels, the increasing use of preoperative and postoperative blood transfusions. Not only was this measure employed more frequently in all cases but also its increasing use in the critically ill who subsequently died indicates more energetic treatment with this accepted measure against the two closely related complications of blood loss and infection. It seems more than a coincidence to relate the lowest mortality rates to the years with the highest incidence of blood transfusion.

As a matter of historical interest, at Harper Hospital, blood transfusions in the early years were performed by the technically difficult direct method of blood transfusion. The introduction of the simple vacoliter method of indirect transfusion relegated the direct transfusion technique to virtual disuse since 1937. The blood bank was established in 1938. The impetus given to blood transfusions by the simplified indirect method and the blood bank is shown in the increased incidence of transfusion since 1937 and 1938. It seems reasonable to us that the increasing use of transfusion has been the largest single factor in the reduction of hysterectomy mortality in our series. The fact that a steadily increasing proportion of patients who died following hysterectomy were transfused is indicative of more intensive and efficient postoperative care and the recognition of the importance of blood loss as a contributing factor in many postoperative complications other than massive hemorrhage. It is heartbreaking to read the case histories of early fatalities which might have been avoided by this means. It is difficult to explain also why blood transfusion was not more energetically employed in a certain number of even recent deaths. Since 1943 blood transfusions have become such a commonplace feature of hospital practice that they are no longer cross-indexed in the hospital record room hence figures for transfusion in hysterectomy are not available for 1944 1945.

Chemotherapy. To evaluate the effect of chemotherapy and antibiotics would require a separate study of each of the 3 537 cases of hysterectomy since 1938 when sulfa therapy was first attempted in one of the patients who died from peritonitis after removal of the uterus. From 1938 to 1945 sulfa therapy was em-

Fig. 2 Mortality percentages. ---- all abdominal hysterectomies o-o-o-o supravaginal hysterectomies — panhysterectomies.

played in 15 of the 37 patients who died during that period 16 deaths during this time being ascribed to peritonitis. In a large proportion of these deaths, particularly in the early years dosage was entirely inadequate as judged by present standards. Most often it was not only too little but also too late. To judge properly the effectiveness of chemotherapy would require an analysis of all morbid cases comparing the results of those treated and not treated by sulfonamides or antibiotics. This method of therapy is not crossindexed in our record room and hence this valuable part of the study was not undertaken. Suffice it to say that despite its obvious benefits other factors in the selection of patients and in preoperative and postoperative care had already lowered considerably the death rate before the beginnings of chemotherapy after 1938 (Fig 2)

Hemorrhage Deaths related to hemorrhage shock and myocardial failure (acknowledging again the questionable justification for including the last, as explained above) accounted for 27 deaths or 0.40 per cent of all hysterectomies. While shock and cardiovascular collapse as a sequence to bleeding still occupy a prominent place among the causes of death listed in Table III, the frequency of this complication shows a demonstrable decline during the succeeding time periods of this series in 1928-1932 it was 0.54 per cent 1933-1940 0.50 per cent 1941-1945 0.20 per cent. This improvement again can probably be explained by the increasing resort to blood transfusion notably since 1936 as shown in Table IV.

Embolism Postoperative embolism accounts for the third major cause of death in this series occurring in 0.20 per cent of all hys-

tributed to fatalities. Of the several possibilities there was only one point concerning which any definite data were obtainable. Two of the 10 deaths of the 1941-1945 series were almost certainly attributable to postoperative intra abdominal hemorrhage. Furthermore, in these cases the thought is inescapable that better treatment in the way of timely reopening of the abdomen probably and more extensive use of blood transfusion more certainly might well have changed the outcome. In another instance, reoperation and replacement of blood lost were successfully accomplished though the patient died of pneumonia 4 days later. Quite possibly the early complication contributed to the fatality. These cases will be mentioned again.

REVIEW OF MORTALITY IN 1941-1945 PERIOD

A review of the deaths in the last 5 years was undertaken with the idea that, in view of the information now available, important points for further improvement might be revealed. In Table II it was shown that in spite of marked reductions the principal causes of death in the 1941-1945 period were the same as in the first that is infection or peritonitis hemorrhage with shock and cardiac failure and pulmonary embolism. These causes, accordingly offered the most fertile field for investigation.

A study of the case histories of the fatalities from peritonitis and infection leaves one with the distinct impression that different treatment might have changed the outcome in the majority. For example, in one case no chemotherapy at all was given and in another it was not started until the day of death. Both of these cases occurred in 1943. In two patients anemia of profound degree was insufficiently treated preoperatively in one and not at all in the other. Moreover in the former a hemoglobin reading of just 40 per cent resulted from the one and only postoperative transfusion. In a fifth patient, 10 grams of sulfanilamide placed in the peritoneal cavity after the bowel therapy and though two blood transfusions were given the resulting hemoglobin level was only 30 per cent. The sixth patient apparently received every possible aid without results be

cause of widespread carcinomatosis peritonitis and coronary thrombosis as shown by postmortem examination.

Of the 4 deaths due to pulmonary embolus there were two of the usual type occurring on the fifth and ninth postoperative days with apparently no suspicion of trouble preceding the accident. Another was stricken when she was to all appearances uneventfully convalescing 12 days after wound disruption and resuture. The fourth died suddenly 15 days after operation during the last 7 of which the patient had been allowed out of bed despite daily temperature elevation ranging between 101.4 and 102.4 degrees. Due to lack of adequate clinical data in these cases comment on the feasibility of vein ligation must be deferred. Certainly in the last case one might seriously question the advisability of amputation in the presence of obvious infection.

Acknowledging again the questionable propriety of grouping deaths from shock hemorrhage and heart failure we repeat that this was done (1) to permit comparison with our first series and (2) because these conditions were difficult of differentiation in certain cases. As an example of the latter a patient with mitral valve insufficiency expired on the operating table in the course of the difficult removal of a densely adherent myomatous uterus. In view of the precarious condition of the patient one might well question the wisdom of undertaking the operation in the first place or of continuing it after the abdomen was opened and the probable dangers were demonstrated. Quite possibly not one week following operation after 36 hours of coronary occlusion but with a considerable possibility of pulmonary embolism as the true cause. Another a 49 year old woman on the eleventh postoperative day and 5 days after secondary wound closure for evisceration died rather suddenly with no pertinent postmortem findings other than moderate basilar lung congestion and acute cardiac dilatation. The two remaining cases were mentioned under the discussion of operative technique as instances of postoperative intra abdominal hemorrhage with the distinct possibility of a different re

sult had treatment been more timely and energetic in the control and replacement of the blood loss.

Of the remaining 4 patients one who was known to have marked hypertensive disease died on the seventh day from renal insufficiency and apoplexy after removal of a fibroid uterus and large ovarian cyst. Another died of uremia 2 weeks after cesarean section and supravaginal hysterectomy for severe premature separation of the normally implanted placenta with marked hypertension (200/120) and albuminuria. The third died in diabetic coma 6 days after operation in spite of all that could be done. The advisability of operation on this patient for a chronic condition even though there was marked disability might be questioned. The last patient was the third case discussed under operative technique. She was successfully operated upon for postoperative and intra-abdominal hemorrhage was transfused adequately but died 4 days later of pneumonia in spite of all treatment. What part the early and probably preventable hemorrhage might have played in initiating the pneumonia cannot be determined.

From this analysis it would appear that in at least 11 of the 19 cases one or more preventable factors featured the preoperative or postoperative care or operative technique which to some degree influenced the fatal outcome. While one must charitably concede mitigating circumstances in certain instances, the faults (notably of omission) in others are obvious, even allowing for the greater wisdom and clarity of hindsight. It seems evident that further improvement of hysterectomy mortality can be attained only by more energetic employment of the factors which we believe accomplished the good results in the latter years of our series. Perhaps it is not too much to hope and expect that by continuation of such treatment the death rate in the next 5 year period will again be reduced 50 per cent.

SUMMARY

A review of the 6 692 abdominal hysterectomies performed at Harper Hospital from 1928 to 1945 inclusive, revealed a marked decline in mortality. In an effort to determine the factors responsible for this improvement, a comparison was made of the results during the first and the last 5 year periods and for the intervening years of the series. This study showed that along with an increase in the numbers of hysterectomies of all types there was also a steady growth in the proportion of total hysterectomies. The mortality curve for the 18 year span demonstrated a consistent lowering of the death rate for hysterectomy from 3.7 per cent in the first 5 year group to 0.78 in 1941-1945. Subtotal hysterectomy mortality declined from 2.8 to 0.76 per cent, while the panhysterectomy deaths dropped from 7.3 per cent to 0.80.

In an investigation of the principal causes of death it was found that while infection, hemorrhage (shock and heart failure) and embolism played the main rôles their incidence in the last 5 year group was greatly reduced over that of the first period. The part played in this reduction by various factors such as better selection of cases, blood transfusion and chemotherapy was considered. It seemed evident that the greatest responsibility in the lowering of hysterectomy mortality was ascribable to the increasing use of blood transfusion. This factor antedated the advent of chemotherapy which probably also caused some improvement though not statistically shown in this series.

An analysis of the last 5 year period in the light of the data derived from this study indicated that in 11 of the 19 deaths a more careful attention to certain potent features of preoperative, operative, and postoperative care might have accomplished a different result. It is suggested that future improvements in mortality rates can be achieved by more energetic application of these beneficial factors.

STRANGULATED FEMORAL HERNIA SURGICAL MANAGEMENT

J PARRAN JARBOE, M.D., and JOSEPH H PRATT M.D. Rochester Minnesota

A FEMORAL hernia is more likely to undergo acute strangulation than is any other type of hernia. Strangulation may occur at any time and often under the most unfavorable circumstances. When a femoral hernia becomes acutely strangulated it constitutes an urgent surgical emergency that requires prompt diagnosis and early operation. The time element is one of the most important factors affecting the prognosis. The seriousness of this disease may be attributed to the frequency with which a segment of small intestine is strangulated and to the rapid development of pathologic degeneration in the constricted portion.

On many occasions emergency operations for acute strangulation in such a situation necessarily are performed by younger surgeons. Often these well trained but less experienced surgeons are somewhat dubious concerning the proper surgical management of strangulated femoral hernia, especially when dealing with the contents of the hernial sac. It is a well known fact that often when circumstances are more unfavorable even the widest surgical experience and judgment may prove to be inadequate and fallacious. The surgeon's decision and technical skills exercised at the operating table may have a profound effect on the end results. Under such confusing and extraordinary conditions the use of certain operative procedures may contribute greatly to the unfavorable postoperative results frequently encountered in the condition under consideration.

Hence, it is essential that every surgeon who performs emergency operations familiarize himself with the accepted methods and technical procedures for overcoming the many problems presented by a strangulated femoral

hernia. For successful management of acute strangulation and to assure a more favorable prognosis it is necessary for the younger surgeon especially to exercise his best surgical judgment and technical skills in adapting routine operative procedures to the individual case.

Many treatments have been proposed for the surgical management of strangulated femoral hernias and each one has its particular advantages. However, because acute strangulation in every instance requires prompt attention and individual consideration the time element does not allow for an appraisal of the many suggested methods of management at the operating table. Unfortunately trial and error treatment is practiced in far too many cases. Perhaps this empirical procedure may be an important factor in the persistence of the high fatality rate in cases of atrangulated femoral hernia.

To learn as much as possible about the management of strangulated femoral hernias a recent comprehensive study of 104 patients treated surgically at the Mayo Clinic during the period from 1907 to 1946 has been made by one of the authors (Jarboe). Believing that the observations and conclusions derived from this review may be helpful to other surgeons in determining the proper surgical management of patients who have acutely strangulated femoral hernia, the authors have collected the investigative findings for discussion. An analysis and evaluation of the surgical management exercised in the 104 cases may be of value in formulating new proposals of treatment that may result in a more favorable outlook for the patient who has a strangulated femoral hernia.

To treat any femoral hernia successfully the surgeon should possess adequate knowledge of the anatomic relationships in the femoral and inguinal regions and he should be familiar with the physiologic and pathologic

Abridgement of portion of thesis submitted by Dr. Jarboe to the faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M. S. in Surgery.

STRANGULATED FEMORAL HERNIA SURGICAL MANAGEMENT

J. PARRAN JARBOE, M.D. and JOSEPH H. FRATT, M.D. Rochester, Minnesota

A FEMORAL hernia is more likely to undergo acute strangulation than is any other type of hernia. Strangulation may occur at any time and often under the most unfavorable circumstances. When a femoral hernia becomes acutely strangulated it constitutes an urgent surgical emergency that requires prompt diagnosis and early operation. The time element is one of the most important factors affecting the prognosis. The seriousness of this disease may be attributed to the frequency with which a segment of small intestine is strangulated and to the rapid development of pathologic degeneration in the constricted portion.

On many occasions emergency operations for acute strangulation in such a situation necessarily are performed by younger surgeons. Often these well trained but less experienced surgeons are somewhat dubious concerning the proper surgical management of strangulated femoral hernia, especially when dealing with the contents of the hernial sac. It is a well known fact that often when circumstances are more unfavorable even the widest surgical experience and judgment may prove to be inadequate and fallacious. The surgeon's decision and technical skills exercised at the operating table may have a profound effect on the end results. Under such confusing and extraordinary conditions the use of certain operative procedures may contribute greatly to the unfavorable postoperative results frequently encountered in the condition under consideration.

Hence it is essential that every surgeon who performs emergency operations familiarize himself with the accepted methods and technical procedures for overcoming the many problems presented by a strangulated femoral

hernia. For successful management of acute strangulation and to assure a more favorable prognosis it is necessary for the younger surgeon especially to exercise his best surgical judgment and technical skills in adapting routine operative procedures to the individual case.

Many treatments have been proposed for the surgical management of strangulated femoral hernias and each one has its particular advantages. However because acute strangulation in every instance requires prompt attention and individual consideration the time element does not allow for an appraisal of the many suggested methods of management at the operating table. Unfortunately trial and error treatment is practiced in far too many cases. Perhaps this empirical procedure may be an important factor in the persistence of the high fatality rate in cases of strangulated femoral hernia.

To learn as much as possible about the management of strangulated femoral hernias a recent comprehensive study of 104 patients treated surgically at the Mayo Clinic during the period from 1907 to 1946 has been made by one of the authors (Jarboe). Believing that the observations and conclusions derived from this review may be helpful to other surgeons in determining the proper surgical management of patients who have acutely strangulated femoral hernia the authors have collected the investigative findings for discussion. An analysis and evaluation of the surgical management exercised in the 104 cases may be of value in formulating new proposals of treatment that may result in a more favorable outlook for the patient who has a strangulated femoral hernia.

To treat any femoral hernia successfully the surgeon should possess adequate knowledge of the anatomic relationships in the femoral and inguinal regions and he should be familiar with the physiologic and pathologic

Fig. Anatomic aspect of femoral hernia, showing a loop of intestine strangulated at the femoral ring.

conditions created by acute strangulation. Since femoral and inguinal hernias often are misdiagnosed it follows that the surgeon must attain to a sound and extensive knowledge of anatomy, physiology and pathology in order to be able to carry out differential diagnosis and proper operative management of the respective herniation.

ANATOMIC ASPECTS

Acute strangulation occurs more frequently in the presence of femoral hernias than in other types because the constricting site is the small rigid femoral ring through which herniation occurs. The oval shaped femoral ring is the internal opening of the femoral canal and it communicates with the abdomen. The femoral ring is bounded laterally by the femoral vein, anteriorly by the inguinal (Poupart's) ligament, medially by the sharp-edged lacunar (Gimbernat's) ligament and posteriorly by the superior ramus of the pubic bone, Cooper's ligament, pectineus muscle and fascia. The short femoral canal extends downward from the femoral ring and terminates at the fossa ovalis which is an aperture in the fascia lata of the thigh that is situated below the midpoint of the inguinal ligament and about 3 centimeters lateral to the pubic tubercle. These anatomic relationships are shown in Figure 1.

When strangulation takes place at the femoral ring the anatomic structures affected

are the hernial sac (formed from parietal peritoneum, preperitoneal tissues and transversalis fascia) and the contents of the sac.

CAUSE OF STRANGULATION

The actual cause of acute strangulation itself is mainly theoretic. It is assumed that femoral herniation occurs with increased intra-abdominal tension that forces the hernial sac and its contents to protrude through the femoral ring. If this herniation is prolonged, the sharp constricting edge of Gimbernat's ligament may inhibit the return of the femoral sac and its contents to the abdomen. Thus, an incarcerated femoral hernia is formed and this may become a strangulated hernia if venous compression and circulatory impairment should follow.

RESULTS OF STRANGULATION

When strangulation occurs, pathologic changes such as congestion, edema, diffuse hemorrhage, necrosis and gangrene take place in the constricted hernial sac. The hernial sac usually is small and globular but these characteristics often are altered by the volume and pathologic condition of the contents of the sac. Since a portion of small intestine is found very frequently in the strangulated hernial sac it is obvious that various degrees of intestinal obstruction often are associated with these hernias.

DIAGNOSIS

Acute strangulation of a femoral hernia is a common cause of acute intestinal obstruction among patients more than 50 years old; hence, the clinical diagnosis should not be difficult if the condition is given adequate consideration. However, the incidence of diagnostic error is high and is at times responsible for delayed operation.

A painful, tense mass in the groin had been present in 100 cases of the 104 concerned herein but the significance of this mass often was misinterpreted and was the commonest diagnostic error. In many cases in which the medical diagnosis was misleading, the patient's objective manifestations indicated to the surgeon the urgent need of immediate operation more so than did the diagnostic impressions.

It was often difficult to make the differential diagnosis between femoral hernia and inguinal hernia, so that in all cases in which the diagnosis was doubtful the latter condition was suspected. In such cases the anatomic relationships of the mass in the groin to the inguinal ligament and pubic spine may be helpful in diagnosis. Usually, a femoral hernia pushes forward and upward to override the inguinal ligament whereas an inguinal hernia makes the ligament more distinct. A femoral hernial mass can be palpated laterally and slightly inferiorly to the pubic spine whereas an inguinal hernial mass is palpated superiorly and medially to the pubic spine.

When a presumptive diagnosis of acute intestinal obstruction is made, especially in aged patients, it is the surgical consultant's ultimate responsibility to examine carefully all external hernial orifices to determine the presence or absence of an acutely strangulated hernia as an etiologic basis for the complaints. Careful examination of the hernial orifices is an important and significant part of every physical examination.

TREATMENT OF STRANGULATION

The one and only treatment for a strangulated hernia is immediate surgical operation. Valuable time should not be sacrificed in an attempt to reduce the strangulation by taxis because the fatality rate increases with each hour that operation is delayed. The prognosis is most favorable when operations are performed within 24 hours after the onset of acute strangulation.

Time element. In the 104 cases under consideration the elapsed time from the onset of acute strangulation until operation ranged from 1 day (fatality rate of 13 per cent) to 4 days (fatality rate of 70 per cent). The importance of the time element in all cases of strangulated femoral hernia cannot be overemphasized. The rapidity with which pathologic changes develop in the contents of the strangulated hernial sac is variable and cannot be ascertained until the sac is opened at operation.

In one case in which operation was performed 2 hours after the onset of clinical manifestations which indicated strangulation

the hernial sac contained a loop of gangrenous small intestine. Generally pathologic degeneration develops slowly but in any case this progression can be interrupted only by surgical release of strangulation. Otherwise irreversible changes occur in the contents of the sac. Usually the responsibility for this unfortunate delay can be attributed to the patient who needlessly sacrifices invaluable time by postponing medical and surgical treatment until his condition becomes critical.

Anesthesia. The method of anesthesia employed for operation depended mainly on the clinical condition of the patient. Before 1932 when spinal anesthesia was first used in operations for strangulated femoral hernia general inhalation anesthesia with ether was the method used most frequently. For 23 critically ill patients local infiltration or regional block anesthesia was used. The lowest fatality rate however was noted in the 32 selected cases in which intraspinal anesthesia was the method of choice.

Because the majority of patients suffering from strangulation of a femoral hernia of several days' duration are very poor operative risks it is essential that each surgeon be thoroughly acquainted with the various anesthetic agents and routes of administration so that this knowledge can be utilized in the proper selection of anesthesia for each patient. In critically ill patients, the damage caused by strangulation and the extent of surgical intervention required cannot be determined preoperatively. For these reasons local infiltration anesthesia or carefully supervised spinal anesthesia is advocated in such instances. However in all cases of acute strangulation the method of anesthesia to be used should be adapted to the patient.

Skin incisions. There has been much comment on the relative merits of different surgical

cal approaches for exposure of a strangulated femoral hernia. The primary skin incisions that were used in operations in this series are listed in Table I.

The primary paramedian and midline incisions were made in 9 cases in which a strangulated femoral hernia was not suspected. In 5 cases a secondary inguinal incision was made when strangulation had been revealed.

Use of the vertical incision over the hernial mass or of the femoral incision below the inguinal ligament has been advocated by some surgeons. A small femoral incision below and parallel to the inguinal ligament gives poor exposure with little opportunity for investigation of intra-abdominal conditions. It is, however, the most rapid method of dealing with this surgical emergency. When it is employed the sac can be identified, exposed and incised and the contents noted—all within a few minutes. To treat the strangulated viscera properly however especially if a portion of small intestine is found in the hernial sac, it is often necessary to make a second incision in the lower part of the abdomen.

The inguinal incision when made 1 to 2 centimeters above and parallel to the inguinal ligament has been the surgical approach most preferred in exposure of a strangulated femoral hernia. According to Watson (1925) the inguinal incision has certain noteworthy advantages over the other approaches: (1) it affords the best exposure of the hernial sac and its contents; (2) constriction is quickly located and relieved; (3) an anomalous obturator artery is noted readily if it is present; (4) intestinal resection and anastomosis can be carried out easily without the exertion of trac-

tion on the mesentery; and (5) the incision permits inspection of the intestine above and below the point of strangulation. This incision however takes more time and is associated with an increased danger of peritoneal contamination with the contents of the hernial sac.

If exposure is adequate and the mesentery is sufficiently mobile intestinal resection and anastomosis necessitated in cases of strangulated femoral hernia should be performed through one inguinal incision. When resection is performed through either a femoral incision or an inguinal incision it should be remembered that prolonged traction on the mesentery often prevents the return of circulation to the bowel and may retard healing processes in the anastomosed loops. Douglas (1912) has pointed out the grave danger of contamination and peritonitis incident to the reduction and resection of a necrotic portion of intestine through a second abdominal incision.

In the series under consideration primary resection and anastomosis of necrotic segments of ileum were performed through an inguinal incision in 7 cases, with 3 deaths (a fatality rate of 43 per cent). Primary resection and anastomosis were performed through a femoral incision below the inguinal ligament in 2 cases. Necropsy in each of the latter cases revealed that insufficient portions of ileum and mesentery had been removed at resection, since there was residual necrosis of both loops of the bowel. Ileal resection and anastomosis were carried out through a secondary paramedian incision in 7 cases, with 5 deaths (a fatality rate of 71.4 per cent).

TREATMENT OF CONTENTS OF HERNIAL SAC

With proper precautions taken to minimize contamination attempts were made to release the constriction and to evaluate the viability of the contents of the sac. To facilitate reduction through the rigid femoral ring it was necessary to incise the lacunar (Gimbernat's) ligament medially in 24 cases. The inguinal (Poupart's) ligament was divided in 18 cases. Both ligaments were severed in 1 instance. An abnormal obturator artery was encountered and ligated on 2 occasions.

Contents of hernial sac. The abdominal and pelvic viscera that were strangulated in the

104 hernial sacs are listed in Table II. That the contents of the hernial sac have a significant effect on the fatality rate is revealed by the fact that in sixty four cases in which a segment or loop of small intestine had been strangulated there were twenty three deaths (a fatality rate of 36 per cent). In the forty cases in which strangulation of abdominal or pelvic structures exclusive of small intestine occurred (Table III) there was one death (a fatality rate of 2.5 per cent).

Viability of contents of sac. After release of the strangulation the determination of viability of the contents of the sac and the subsequent surgical treatment were considered. In 40 cases in which abdominal or pelvic structures exclusive of the small intestine were strangulated the decision as to viability was not difficult to make. Viability of the urinary bladder, cecum and sigmoid colon was assured after reduction of strangulation. The constricted portions of other structures (omentum, appendix, Meckel's diverticulum, adenomyoma and endometrial hematoma) were excised without incident in nearly all cases.

When a segment of small intestine had been strangulated in the hernial sac, determination of viability of the involved bowel after reduction was much more difficult, especially in cases in which the condition was intermediate. Viability was determined by observance of the return of arterial pulsations in the mesentery, and the return of a normal pink color and serosal luster to the affected segment of bowel. This physiologic recovery was stimulated by means of the application of warm saline compresses to the affected parts and by having the patient breathe pure oxygen. If circulatory improvement was not noted within 15 minutes the affected portion of bowel was considered to be nonviable.

These procedures for determination of the viability of involved bowel consume valuable time and prolong the operation unnecessarily. Consequently, after successful experimental and clinical trials in 500 cases, Herrlin, Glasser and Lange in 1942 proposed two methods for determination of the viability of strangulated bowel when viability is doubtful.

Method 1 — Fluorescein test.—After the doubtful, fully viable segment of bowel has been exposed, 3 to

6 cubic centimeters of a 5 per cent solution of fluorescein is injected intravenously. The operating room is darkened and the bowel is observed under ultra violet light. Viable bowel produces a golden-green illumination; a nonviable segment remains dark.

Method 2 — Procarine test.—When amounts up to 10 cubic centimeters of a 2 per cent solution of procarine hydrochloride are injected locally around the mesenteric blood vessels, there is an immediate release of any vasospasm present, resulting in hyperemia and rapid improvement in circulation to the affected segment of bowel.

These investigators reported that these methods can be used singly or together with accuracy of 90 per cent for ascertaining the viability of bowel. They can be used therapeutically for improvement of the circulation to questionable portions. Although these procedures were not used in any cases of the series concerned herein, perhaps they deserve special consideration and utilization in future deter-

minations of viability of the bowel in doubtful areas.

When viability of the contents of the hernial sac was determined at operation methods were instituted for treatment of the nonviable portions of the strangulated viscera. Naturally the surgical management depended on several factors such as the amount of viscus strangulated within the hernial sac and the pathologic condition of the viscus concerned at the time of reduction.

To demonstrate the advantages or disadvantages of certain operative procedures commonly used in the surgical management of strangulated portions of small intestine the operative details of each case in the 104 concerned herein were reviewed and classified accordingly. The operative procedures used in the 104 cases and the hospital fatality rates associated with each procedure are summarized in Table III.

Fatality rate after treatment of contents of hernial sac. Strangulated and nonviable segments of ileum were removed in 16 cases with 10 deaths (a fatality rate of 62.5 per cent). In 10 cases the viability of the strangulated portion of small intestine was questioned but because of the patient's poor condition the segment was not removed. In these 10 cases there were 9 deaths (a fatality rate of 90 per cent). An obvious conclusion should be that although the fatality rate associated with primary ileostomal resection is high the fatality rate is much higher when questionably viable segments of bowel are returned into the abdomen without resection.

The high fatality rate associated with intestinal resection in the management of strangulated femoral hernia has been recognized and reported by many surgical investigators. Braun and Wortmann in 1924 reported a fatality rate of 50.4 per cent in cases in which resection was carried out. Frankau in 1931 reported a fatality rate of 42.8 per cent in such cases. McClure and Fallis in 1939 reported a fatality rate of 66.7 per cent. McNeely, Lichtenstein and Todd in 1942 reported a rate of 60 per cent and Jens in 1943 reported a fatality rate of 66 per cent in cases in which strangulated femoral hernia required resection of the small bowel. The fatality rate of

62.5 per cent associated with resection in this series thus compares favorably with other reported statistics.

In 40 of the 104 cases viscera other than the small intestine were strangulated in the hernia. The operative procedures used in the treatment of strangulated segments of the small intestine in the remaining 64 cases will be described and discussed separately. In this group of 64 cases, postmortem examination was performed in 20 of the 23 cases in which death occurred. A study of the necropsy reports has made possible practical evaluation of certain operative procedures and surgical judgments exercised at the primary operations.

The gangrenous portion of ileum was removed, anastomosis was carried out and the abdomen was closed without drainage in 7 cases, with 4 deaths (57 per cent). In addition to primary resection and anastomosis in 7 other cases an enterostomy tube was inserted into the proximal loop of the distended bowel. In these latter 7 cases there were 5 deaths (71.4 per cent). The removed portions of ileum and mesentery were from 6 to 45 centimeters long.

In 2 cases the gangrenous segment of ileum was exteriorized and removed according to a modified Mikulicz procedure and there was 1 death (50 per cent). In each case an enterostomy tube was inserted into the proximal portion of the exteriorized loop of bowel.

Intestinal anastomosis. After the necrotic segments of ileum and mesentery had been removed primary ileoileostomy re-established continuity of the small bowel in 14 cases. Side-to-side anastomosis was carried out in 6 cases, with 3 deaths (50 per cent). End-to-end anastomosis was performed in 8 cases, with 6 deaths (75 per cent).

Postmortem examination in 3 of the 8 cases in which end-to-end ileoileostomy had been performed revealed almost complete obstruction of the bowel at the site of anastomosis, in addition to leakage of foul liquid material through the gaping suture holes into the peritoneal cavity.

In 2 of the cases in which side-to-side anastomosis had been established results of necropsy indicated that the union had been satisfactory in one instance, but that in the other the stoma had been inadequate and had

caused partial obstruction with some distention of the proximal ileal loops. No evidence of leakage was reported.

On the basis of the end results in these cases it might be concluded that after removal of the nonviable segment and inversion of the cut ends of bowel re-establishment of intestinal continuity by side-to-side anastomosis is a safe surgical procedure especially for less experienced surgeons who might otherwise encounter considerable difficulty in anastomosing a distended hyperemic proximal loop end-to-end to the collapsed distal loop of bowel.

For the surgeon who encounters this type of hernia only occasionally side-to-side anastomosis has some advantages. (1) it permits satisfactory anastomosis of a dilated proximal loop of bowel to a collapsed distal segment with less danger of leakage of the fluid contents of the bowel into the peritoneal cavity. (2) the large stoma which is created assures adequate drainage of the distended proximal loops of bowel and reduces the possibility of subsequent obstruction at the stomal site. and (3) at the time the anastomosis is carried out overlapping of the mesenteries assures adequate circulation to the site of anastomosis. However the oblique end-to-end type of anastomosis when performed in selected cases by more experienced and adept surgeons readily restores physiologic continuity to the intestine without the delay for readjustment that is often encountered after other types of anastomoses have been performed.

Enterostomy. After removal of the necrotic portion of ileum and primary anastomosis had been performed drainage of the proximal loops of bowel by enterostomy tube was established in 7 cases with 5 deaths (71.4 per cent). Necropsy carried out in 4 cases demonstrated that in each case the enterostomy tube had been inserted about 10 to 15 centimeters proximal to the site of anastomosis. In 2 cases necrosis and sloughing of the wall of the bowel around the tube had resulted with leakage of much foul fluid into the peritoneal cavity. In another instance the ileum was obstructed completely at the site of the enterostomy.

In 7 cases in which the strangulated portion of bowel was doubtfully viable but was not removed enterostomy drainage was instituted

and there were 5 deaths (71.4 per cent). Of 14 cases in which enterostomy drainage had been established necropsy in 10 revealed necrosis of that portion of bowel around the tube and leakage of foul fluid into the peritoneal cavity in nearly all cases. In 2 cases marked constriction about the enterostomy tube had caused partial intestinal obstruction.

On the basis of the foregoing facts it might be concluded that in cases of strangulated femoral hernia with inextensive intestinal obstruction the establishment of drainage by enterostomy tube in the proximal portion of distended bowel greatly increases the operative risks. With ample consideration of the inherent dangers concomitant to the establishment of enterostomy drainage, increased efforts should be directed toward decompression of distention of the small bowel by other means. The use of Wangensteen's nasal suction apparatus or some modification such as the Miller Abbott or Wilson Sawyer double lumen tubes for continuous drainage of the small bowel from the moment intestinal obstruction or distention is recognized should obviate any need for enterostomy.

Exteriorization. The strangulated and gangrenous loop of ileum was exteriorized and secondarily removed in 2 cases with 1 death.

The necrotic loop of small intestine was exteriorized but not removed in 2 cases both patients succumbed. One patient died of diffuse peritonitis incident to replacement of the exteriorized loop into the abdomen 10 days after the first operation.

If the exteriorized nonviable loop of bowel is not removed primarily the source of proteolytic toxins formed from necrotizing tissues remains so that fatality may result from the toxemia alone. Although a primary removal of nonviable portions of strangulated bowel followed by anastomosis is the preferred surgical treatment, exteriorization and immediate removal of the strangulated loop is an alternative procedure when further surgical treatment is contraindicated. The risk of removal of the exteriorized loop of bowel is considerably less than that incident to replacement of the loop within the abdomen.

Invagination. There were 16 cases of Richter's hernia in which only a portion of the wall

of the small bowel was constricted within the femoral ring. In 5 of these cases the strangulated portion was invaginated into the lumen of the bowel. There were 4 deaths in these 5 cases (80 per cent). Several inverting Lembert sutures (Summers' stitch) were placed in the seromuscular layers of the adjacent normal portion of bowel so that the serosal layers were approximated over the inverted necrotic portion.

Necropsy showed definite constriction and intestinal obstruction at the site of inversion in 3 instances. Extensive necrosis of bowel and mesentery above and below the inverted segment with perforation and leakage at the site of inversion was found in the fourth case of the aforementioned five.

On the basis of these observations, it would seem that simple inversion of a small necrotic portion of the wall of the bowel is a procedure of questionable value in the surgical management of strangulated femoral hernia. When a nonviable segment is revealed the results indicate that it is advisable to take the extra time necessary to perform primary resection and anastomosis, rather than to invert the strangulated segment of bowel and thereby produce more obstruction.

When abdominal or pelvic viscera other than portions of the small intestine had been strangulated in the hernial sac the surgical management was directed primarily toward release of strangulation and reduction of the contents of the sac. Radical resection was unnecessary and thus the greatly diminished operative risk in these cases is reflected in the low fatality rate of 2.5 per cent.

TREATMENT OF THE HERNIAL SAC

When the contents of the hernial sac had been reduced and treated the sac itself was treated. In the majority of cases and especially when a portion of the small intestine had been strangulated the hernial sac was damaged to a lesser degree than its contents. However the sac was congested and edematous in nearly all cases and this increased the difficulties of its surgical management.

In 77 cases the hernial sac was closed at the neck by either a pursestring suture or simple ligature. It was then excised. When the in-

guinal approach was used the stump of the sac was often transfixed under the conjoint tendon. In 8 cases the stump was simply inverted as is done in the treatment of the sac of a direct inguinal hernia. When the sac was ligated and excised from below the inguinal ligament the neck was freed from the femoral ring and the stump was allowed to retract upward under the transversalis fascia.

In this series, the method of closure of the hernial sac apparently had little effect on the success of the operation although a femoral hernia recurred in 2 instances in which the sac had been ligated from below the inguinal ligament. It would seem that high ligation of the hernial sac with fixation of the stump under the conjoint tendon offers ample insurance against subsequent femoral or direct inguinal herniation.

REPAIR OF THE HERNIA

The basic methods employed for surgical repair of the femoral hernia depended on the anatomic approach either from above or below the inguinal ligament. More than 60 different operations have been enumerated for repair of a femoral hernia. Many plastic operations for filling the femoral canal by muscular peritoneal omental and heteroplastic flaps, are wrong in principle and have obtained little support whereas the simpler operations for obliteration of the femoral canal and closure of the femoral ring have prevailed.

The femoral hernia was repaired in 80 cases of the series of 104 but often the methods used were not specified. In 24 cases in which the surgical risk was excessive, the release of strangulation and treatment of the contents of the sac were more important than the method of repair of the hernia.

In 4 cases in which strangulation was treated through a femoral approach below the inguinal ligament the femoral ring and femoral canal were not repaired surgically, an action which was in accord with the procedure recommended by Ochsner in 1906. It was assumed that after reduction of the femoral hernia and ligation of the sac the femoral vein would re-expand gradually to come into contact with Gimbernat's ligament thus obliterating the femoral canal. When this method

was used however femoral hernia recurred in 2 cases

Repair of the femoral hernia was performed from below the inguinal ligament in 15 cases. In 7 closure of the femoral ring and canal was achieved by a single Coley stitch in which a pursestring suture of chromicized catgut was placed to approximate the inguinal ligament medial wall of the femoral vein pectineus muscle and fascia and Gimbernat's ligament. In the other cases, the pectineus muscle and fascia and the lower edge of Gimbernat's ligament were approximated to the inguinal ligament with the use of one to four chromicized catgut mattress sutures. The surgeon avoided the infliction of trauma to the femoral vein by retracting it with his index finger while the sutures were being placed. This procedure obliterates the femoral ring and canal without constriction of the femoral vein.

After reduction and treatment of strangulation had been carried out the femoral hernia was repaired from above the inguinal ligament in 65 cases. One of the following procedures was employed in each case.

Simple closure Simple closure of the femoral ring included the use of a pursestring suture to approximate the inguinal ligament medial wall of the femoral vein Cooper's ligament and Gimbernat's ligament. One recurrence followed this type of hernial repair.

Moschcowitz type of operation In the performance of this operation the inguinal ligament was sutured to Cooper's ligament.

Lothessen's or some modification of Annandale's original inguinal operation In the performance of this operation the conjoined tendon the mobilized rectus sheath external oblique aponeurosis or the transversalis fascia was sutured to Cooper's ligament. This placed a firm musculofascial barrier over the femoral opening to inhibit any subsequent femoral or direct inguinal herniation. The ultimate success of this operation depended on sound healing of the apposed structures, which often were out of alignment or were sutured under tension.

When the inguinal approach was used the operation usually was concluded with surgical repair of the inguinal canal. If the internal inguinal ring was enlarged or if there was

muscular relaxation in Heesselbach's triangle then the spermatic cord (round ligament in females) was transplanted subcutaneously and the external oblique aponeurotic flaps were imbricated beneath it.

SEQUELAE

In the 80 cases in which the femoral hernia was repaired there have been 3 known recurrences (a rate of 3.8 per cent). In addition direct or indirect inguinal hernias have developed on the same side in 3 patients. In each of the latter cases the femoral hernia had been repaired from below the inguinal ligament. Perhaps if the inguinal operation had been done originally any relaxation of the internal inguinal ring or muscular weakness of the inguinal canal might have been recognized and repaired then.

COMMENT

Many of the problems presented by a strangulated femoral hernia have persisted in spite of previous studies. Just what constitutes 'proper surgical management' of a strangulated femoral hernia is one of the problems the answer to which is dependent on the many circumstances of each case. No specific routines of management can be elaborated which will overcome effectively the many barriers and handicaps presented by any 2 cases of strangulated femoral hernia.

In the management of acute strangulation the surgeon's ingenuity frequently is challenged by the confusing and changing circumstances enveloping each case. Even for experienced surgeons the best judgment and technical skill often prove faulty and inadequate. But with reliance on the acquired knowledge of the anatomic physiologic and pathologic elements involved in strangulation the obstacles may be removed one by one and the operative results should be gratifying.

Some of the conflicting and confusing circumstances concerning the surgical management of strangulated femoral hernia have been presented and discussed in this paper. The authors hope that the observations and conclusions will be helpful to other surgeons who may be confronted with this condition at the operating table.

of the small bowel was constricted within the femoral ring. In 5 of these cases the strangulated portion was invaginated into the lumen of the bowel. There were 4 deaths in these 5 cases (80 per cent). Some of the conflicting and confusing circumstances concerning the surgical management of strangulated femoral hernia have been presented and discussed in this paper. The authors hope that the observations and conclusions will be helpful to other surgeons who may be confronted with this condition at the operating table.

SUMMARY AND CONCLUSIONS

A comprehensive review of the problems presented in 104 cases of strangulated femoral hernia has been made by one of the authors (Jarboe). It has been demonstrated that the surgical management is dependent on and determined by the clinical and pathologic conditions in each case. The most commonly used operative procedures have been appraised and evaluated. The responsibility for the unfavorable results often encountered has been attributed to the respective causative factors when possible.

From this study of the surgical management in 104 cases of strangulated femoral hernia a number of observations and conclusions may be derived.

First acute strangulation of a femoral hernia is a serious surgical emergency condition in which the time element is an important factor affecting the surgical management and ultimate prognosis.

Second a tense painful mass in the groin especially when it is associated with clinical evidence of acute intestinal obstruction must be considered a strangulated femoral hernia until proved otherwise by operation.

Third the inguinal operation for strangulated femoral hernia is recommended.

Fourth primary removal which is followed by anastomosis is advocated when a segment of small intestine is strangulated and nonviable.

Fifth when the viability of a strangulated viscus is questionable the risk of removal of the involved part is less than the risk of replacement of nonviable structures in the abdomen.

Sixth extirpation and the immediate removal of the necrotic portions of bowel are alternative procedures in those cases in which additional surgical treatment is contraindicated.

Seventh the inguinal operation with repair of the femoral and inguinal canals, offers the best insurance against recurrent femoral or inguinal herniation.

THE MECHANISM OF PRODUCTION OF LINEAR SKULL FRACTURE

Further Studies on Deformation of the Skull by the "Stresscoat" Technique

E. S. GURDJIAN M.D. F.A.C.S. H. R. LISSNER M.S. and J. E. WEBSTER M.D.
Detroit, Michigan

THE application of the stresscoat technique for the determination of strains following blows upon the skull has been described previously (1). The path and pattern of strains on the external surface of the skull following blows of known energy were studied and have been reported upon (2, 3). In the present contribution the strain paths on the external and internal surfaces of the skull have been studied simultaneously. The configuration of strain patterns on the internal surface of the skull are most revealing and help to formulate a more complete view of the mechanism of linear fracture from general deformation of the skull in head injury.

PROCEDURE

Fresh cadaver skulls were obtained from the anatomical laboratory of Wayne University, College of Medicine. The skulls were boiled for several hours to facilitate the removal of skin, muscles, dura, etc. The dura usually could be pulled loose and removed in several large pieces by working with long forceps through the foramen magnum. After drying for several hours the skulls were washed thoroughly with ether.

The skulls were now coated inside and out with a thin coat of aluminum lacquer which gives a uniform background for the stresscoat. After a drying period of 15 to 20 minutes, the skulls were sprayed with the stresscoat. A lacquer was chosen which had a strain sensitivity of 0.0005 to 0.0010 inch per inch for the prevailing temperature and humidity

conditions. Spraying of the interior of the skull was accomplished by means of an 8 inch extension rod attached to the spray gun. The extension was inserted through the foramen magnum. This method was found to be the best of several tried to coat the interior of the skull. Another method consisted of mounting the skull on a turntable and rotating it at a constant rate while directing the spray over the internal surface. However, it was found that the best results were obtained by manipulating the skull in one hand and directing the spray at the same time with the other. With a little practice it was possible to obtain a coating of a reasonably uniform thickness over practically all of the internal surface. Several calibrating strips used to determine lacquer sensitivity were run with each test.

The lacquer was permitted to dry for 24 hours before testing. The skulls were suspended above a polished steel block weighing several hundred pounds by means of a silk thread. The thread was tied around the skull in such a manner that when the skull was dropped it hit the steel slab so that the center of gravity of the skull was vertically above the point struck. Also care was taken to see that the blow was delivered normal to the surface being struck. The weight of the skull and the distance through which it was dropped determine the amount of energy absorbed. These experiments were carried out with a constant energy of 16 inch pounds. After hitting the steel surface the skull was caught on the rebound to prevent damage to the lacquer from secondary bounces.

The skull was now sawed in two by means of an electric circular bone saw. The bisection was carried out in such a way that it would not

SUMMARY AND CONCLUSIONS

A comprehensive review of the problems presented in 104 cases of strangulated femoral hernia has been made by one of the authors (Jarboe). It has been demonstrated that the surgical management is dependent on and determined by the clinical and pathologic conditions in each case. The most commonly used operative procedures have been appraised and evaluated. The responsibility for the unfavorable results often encountered has been attributed to the respective causative factors, when possible.

From this study of the surgical management in 104 cases of strangulated femoral hernia a number of observations and conclusions may be derived.

First acute strangulation of a femoral hernia is a serious surgical emergency condition in which the time element is an important factor affecting the surgical management and ultimate prognosis.

Second a tense painful mass in the groin especially when it is associated with clinical evidence of acute intestinal obstruction must be considered a strangulated femoral hernia until proved otherwise by operation.

Third the inguinal operation for strangulated femoral hernia is recommended.

Fourth primary removal which is followed by anastomosis, is advocated when a segment of small intestine is strangulated and nonviable.

Fifth when the viability of a strangulated viscus is questionable, the risk of removal of the involved part is less than the risk of replacement of nonviable structures in the abdomen.

Sixth exteriorization and the immediate removal of the necrotic portions of bowel are alternative procedures in those cases in which additional surgical treatment is contraindicated.

Seventh the inguinal operation with repair of the femoral and inguinal canals, offers the best insurance against recurrent femoral or inguinal herniation.

Fig 2 A frontal blow to the left of the midline. On the external surface of the skull are seen cracks in the lacquer extending downward toward the nose and the roof of the orbit to the right of the midline. On the internal surface of the skull there is a series of cracks in the lacquer forming a star with some cracks crossing the midline and extending downward toward the anterior fossa.

dropped and the sensitivity of the lacquer are given. Deceleration blows were studied in the following positions (1) frontonasal junction at the midline (2) midfrontal (3) frontal region lateral to the midline (4) lateral frontal (5) midline anterior interparietal (6) temporo-parietal (7) lateral parietal (8) midline posterior interparietal (9) lambdoid suture neighborhood halfway between midline and mastoid and (10) midline occipital. In some locations more than one skull was used. The resultant patterns are briefly described and can also be seen in the accompanying figures.

Frontonasal blow at the midline. Following a blow at the frontonasal junction at the midline the area of contact was butterfly shaped and it involved the frontal bone on both sides of the midline just above the orbits. On the internal surface of the skull, an irregular star pattern was noted somewhat disjointed by the midline frontal buttress. On the external surface there were some cracks in the lacquer surrounding the area of impact and others extending into the roof of the orbit on both sides. On more than one occasion such a blow was associated with contrecoup cracks in the lacquer at the base of the skull near the foramen magnum. These cracks traversed the

occipital bone in the anteroposterior direction (Fig 1)

Midfrontal blow. After a midfrontal blow on the external surface of the skull there were cracks in the lacquer extending toward the roof of the orbit on one or both sides with some cracks along both frontosphenoid junctions. In Figure 2 a midline frontal blow is characterized by a star pattern on the internal surface with cracks in the lacquer extending across the forehead to the roof of the orbit on the external surface of the skull. The external cracks begin as the internal pattern ends. In Figure 16 a midfrontal blow near the bregma is represented with the internal pattern in red and the external cracks in black. There is an outbending of the skull peripheral to the area of mbending in the region of impact. The outbending occurs in at least two planes in the right forehead in the superoinferior plane, and in the left forehead the outbending is obliquely from side to side.

Frontal blow lateral to the midline. On the interior of the skull a star shaped series of cracks in the lacquer are noted. On the exterior of the skull there are cracks in the lacquer extending toward the roof of the orbit and the lateral frontal region. The external

Fig. A midfrontal blow at the occiput. In the upper left cracks are seen in the lacquer surrounding the area of impact and extending across the midline. The ones inferior to the area of impact further extend to the medial and superior wall of the orbit on both sides. This is better seen in the upper right. In the lower left, starlike pattern is noted on the internal surface of the skull. This pattern is definitely interrupted by the midfrontal buttress. In the lower right cracks are seen in the lacquer covering the squamous portion of the occipital bone and extending toward the foramen magnum. These may be considered concentric type.

interfere with the deformation patterns obtained. The sawing itself did not produce cracking of the lacquer in any case.

The deformation patterns were next developed with red dye etchant applied for about 40 seconds and then removed with the etchant emulsifier. The dye penetrated any cracks

that formed as a result of the blow. They were traced with India ink and photographed.

In Table I the number of the experiment, the location of the blow, the weight of the skull, the distance through which it was

Fig. 2. A frontal blow to the left of the midline. On the external surface of the skull are seen cracks in the lacquer extending downward toward the nose and the roof of the orbit to the right of the midline. On the internal surface of the skull there is a series of cracks in the lacquer forming a star with some cracks crossing the midline and extending downward toward the anterior fossa.

dropped and the sensitivity of the lacquer are given. Deceleration blows were studied in the following positions: (1) frontonasal junction at the midline, (2) midfrontal, (3) frontal region lateral to the midline, (4) lateral frontal, (5) midline anterior interparietal, (6) temporo-parietal, (7) lateral parietal, (8) midline posterior interparietal, (9) lambdoid suture neighborhood halfway between midline and mastoid, and (10) midline occipital. In some locations more than one skull was used. The resultant patterns are briefly described and can also be seen in the accompanying figures.

Frontonasal blow at the midline. Following a blow at the frontonasal junction at the midline the area of contact was butterfly shaped and it involved the frontal bone on both sides of the midline just above the orbits. On the internal surface of the skull an irregular star pattern was noted somewhat disjointed by the midline frontal buttress. On the external surface there were some cracks in the lacquer surrounding the area of impact and others extending into the roof of the orbit on both sides. On more than one occasion such a blow was associated with contrecoup cracks in the lacquer at the base of the skull near the foramen magnum. These cracks traversed the

occipital bone in the anteroposterior direction (Fig. 1).

Midfrontal blow. After a midfrontal blow on the external surface of the skull there were cracks in the lacquer extending toward the roof of the orbit on one or both sides with some cracks along both frontosphenoid junctions. In Figure 2 a midline frontal blow is characterized by a star pattern on the internal surface with cracks in the lacquer extending across the forehead to the roof of the orbit on the external surface of the skull. The external cracks begin as the internal pattern ends. In Figure 16 a midfrontal blow near the bregma is represented with the internal pattern in red and the external cracks in black. There is an outbending of the skull peripheral to the area of inbending in the region of impact. The outbending occurs in at least two planes: in the right forehead in the superoinferior plane, and in the left forehead the outbending is obliquely from side to side.

Frontal blow lateral to the midline. On the interior of the skull a star-shaped series of cracks in the lacquer are noted. On the exterior of the skull there are cracks in the lacquer extending toward the roof of the orbit and the lateral frontal region. The external

Fig. 3. Left frontal blow. In the upper left photograph, cracks can be seen in the lacquer extending downward toward the roof of the orbit and continuing on along the superior wall of the orbit. Most of these occur on the left side. A few cracks are also seen in the frontonasal junction. These also extend toward the roof of the orbit. In the upper right photograph the pattern surrounding the area is better seen with some cracks also noted superiorly and medially. In the lower left, the lateral view of the skull on the left side discloses the strain patterns extending downward and posteriorly toward the temporal bone. There are also some cracks in the lacquer in the sphenotemporal bone just above the zygomatic arch. In the lower right, the internal surface of the skull shows a star pattern with cracks extending for longer distances medially than laterally. This arrangement can be explained by virtue of the fact that the radius of curvature laterally changes much more abruptly than medial to the star pattern.

cracks appear at a point where the cracks on the internal surface end. A frontal blow lateral to the midline involved mainly the orbit on the same side but a few cracks were found crossing the nasion to the opposite side (Fig. 3).

Lateral frontal blow. On the internal surface a well formed star more extensive in the anteroposterior direction than from above downward is noted. On the external surface a series of cracks extend down toward the temple and a few also involve the zygomatic arch. Again the external cracks begin just where the internal cracks end (Fig. 4). In Figure 17 a

composite representation of the internal and external patterns is given. The red colored lines represent the internal pattern and the black lines are those found on the external surface of the skull. Note that the black lines begin where the red lines have just ended. An unbending about the area of impact and an unbending in the anterior temple producing strains in the anteroposterior direction can be noted.

Midline anterior interparietal blow. Following a midline anterior interparietal blow the skull showed a star shaped series of cracks on

*Skull too thick, no star pattern obtained.

its internal surface somewhat more extensive anteriorly and longer in the left lateral direction. This was associated with cracks in the lacquer appearing on the external surface of the skull in such a manner that the external cracks dovetail with the internal ones. The most prominent external cracks are those extending perpendicularly downward toward the temple on both sides (Fig 5). In Figure 18 the internal (red) and the external (black) patterns are reprinted together. Note that the region about the point of impact is indented in an asymmetrical manner. This is in turn surrounded by an outbending of the skull with strains on the anteroposterior direction in the parietotemporal neighborhood and from side to side posterior to area of indention.

Fig. 4. A lateral frontal blow left frontal parietal junction. In the upper photograph cracks in the lacquer downward toward the temple are seen and a few cracks are also seen on the zygomatic bone and arch arranged radially. On the internal surface, in the lower photograph, a star pattern is again noted. This star is much more extensive anteroposteriorly than superoinferiorly. In Figure 17 when the patterns on the internal and external surface of the skull are superimposed, it becomes apparent that the external patterns appear at the border of the internal patterns.

Temporoparietal blow On the internal surface the usual star with fairly long extensions anteriorly and fairly limited propagation superoinferiorly is noted. This region is surrounded on the outside of the skull with cracks in the lacquer extending downward and forward toward the temple others extending posteriorly toward the midline and still others superiorly toward the midline. Corresponding to the border of the star pattern on the internal surface of the skull there are circular lines on the external surface. Some cracks in the lacquer at the base on the same side are also seen (Fig 6).

Fig. 5. Anteroparietal blow at the midline near the frontoparietal junction (bregma). The upper left photograph shows the strain pattern on the superior surface of the skull. Several discreet groups of cracks are seen extending laterally and downward. Another group extends posteriorly to the midline. In the lower left figure the cracks appearing on the lateral surface of the skull are seen coursing toward the temple on the left. The same configuration is noted on the right side. On the anterior of the skull seen in the photograph to the right, star pattern is again noted with more marked propagation along the anterior midline and laterally on either side, with rather abrupt stoppage of the pattern posteriorly to the midline. On careful superimposition, and as seen in Figure 8, the pattern on the internal surface of the skull fits in between the group of cracks in the lacquer seen on the external surface of the skull.

Lateral parietal blow In one specimen only a star on the internal surface of the skull was noted with no pattern on the outside except for a few cracks on the anterior temporal region. It should be noted that this is a rather thick skull (Fig. 7). Again the anteroposterior dimensions of the star are much more extensive than the superoinferior. In Figure 8 a series of cracks appear on the external surface

of the skull suggesting a strain anteroposteriorly in front superoinferiorly in the temporal bone and anteroposteriorly in the posterior inferior parietal region. Note that the strains in the posterior inferior parietal region are about at right angles to the strains occurring in the anterior parietal region near the temporal bone. On the internal surface the star pattern dovetails with the exter-

Fig. 6. Temporoparietal blow on the right side. In the upper left there is an area of lacquer surrounding the impact which is devoid of cracks. This is in turn surrounded by circular cracks which extend downward and forward in the anterior and inferior portions, upward and forward superiorly downward and backward posteriorly.

nal pattern. In Figure 9 an irregular star is seen on the internal surface with cracks in the lacquer extending downward and forward on the external surface. In this specimen there is also a contrecoup deformation of the left lateral frontal region with cracks appearing only on the external surface suggesting an outbending of the skull in this region. In Figure 10, the pattern following a posterior parietal blow near the midline is shown. On the external surface of the skull a few cracks extending downward and forward are seen. On the internal surface a well formed star pattern is shown. The external cracks begin where the lines of the internal pattern end.

Midline posterior interparietal blow. On the external surface no patterns are noted but on

In the lower left, there are some cracks at the base of the skull as far as the basilar portion of the occipital bone. In the photograph to the right the internal surface of the skull shows a star formation with the cracks extending anteriorly for longer distances than superoinferiorly.

the internal surface a star pattern is seen (Fig 11).

Blow on lambdoid suture neighborhood half way between midline and mastoid. In Figure 12 the pattern of a posterior parietal blow near the lambdoid suture is shown. On the external surface of the skull cracks in the lacquer extend down toward the base and the mastoid region. A few cracks appear in the anterior temporal region near the frontozygomatic junction on both sides. On the internal surface a star pattern is noted. The external lines in the lacquer begin where the cracks of the internal star pattern end. In Figure 13 an extensive star is noted on the internal surface of the skull again showing greater length in the anteroposterior direction than superoin-

Fig. 7 Right lateral parietal blow. This thick skull shows no cracks of the lacquer on its external surface. On the internal surface of the skull, in the lower photograph, the usual star is again seen, with anterior extensions much more widespread than superolaterally.

teriorly. On the external surface cracks appear in the lacquer extending toward the base of the skull on the right side, lateral to the foramen magnum.

Midline occipital blow near lambdoid suture
In Figure 14 the blow was somewhat to the right of the midline with a beautiful star pattern on the internal surface of the skull limited on the medial and inferior portions by the midline occipital buttress. On the external surface of the skull there are some cracks extending toward the mastoid and others extending toward the foramen magnum. In Figure 15 a nice pattern is noted on the internal surface with irregularity in contour and this pattern fits almost exactly the area of the skull on the external surface not showing any

Fig. 8 Right lateral parietal blow. On the external surface the point of impact is surrounded by an area devoid of cracks of the lacquer. This corresponds to the star pattern on the internal surface of the skull. Outbending strains are at least in three directions. Forward they are obliquely in the superolateral direction, below they are in the superior inferior direction and behind, in the anterior posterior direction. The lateral pattern is cut short superiorly due to the curving of the skull.

cracks in the lacquer. The point of impact is surrounded by masses of cracks anteriorly laterally and posteriorly in such a manner as to suggest a most interesting pattern of deformation of an undulating type governed in part by buttresses and variations in thickness. In Figure 19 the red lines represent the internal pattern and the black lines the external cracks in the lacquer. Note the way the internal and external patterns dovetail.

Fig. 9. Right posterior parietal blow. This set of photographs is included in order to emphasize the contrecoup pattern seen in the skull to the right. The cracks in the lacquer appeared only on the external surface of the skull and they occur just superior and posterior to the zygomaticofrontal junction. The upper photograph to the left

shows a pattern on the internal surface of the skull of an irregular star with anterior extensions several times longer than the cracks superoinferiorly. In the lower left, there is extensive deformation pattern evidenced by cracks in the lacquer extending downward and forward.

DISCUSSION

It should be re-emphasized that this method shows only tensile strain patterns (tearing apart). Compression strains (pushing together) cannot be visualized in these studies. However, when both external and internal surfaces of the skull are available for study bending activity can be determined. Bending produces tension on one surface and compression on the other. Thus in a region where cracks are found on one surface of the skull and not on the other bending has occurred as indi-

cated by the position of the cracks. Cracks on the external surface of the skull indicate outbending while cracks on the internal surface indicate a region of inbending.

Following a deceleration impact there is an area of inbending the limits of which are governed by the radius of curvature of the skull in the region of impact. At times this area of inbending is of irregular outline due to irregularities of thickness, presence of buttresses and other factors such as emissary foramina and diploic channels of unusual ex-

Fig. 6. Posterior parietal blow. On the external surface, there are cracks extending downwards and forwards toward the temple. On the internal surface, a beautiful star pattern is seen. The external cracks begin where the internal cracks end.

Fig. 7. An interparietal blow at the midline near the lambdoid suture. The left photograph shows no pattern on the external surface of the skull. The right photograph shows a star pattern on the internal surface of the skull somewhat interrupted by the midline buttress.

tent. Peripheral to the area of inbending the bone bends out simultaneously in certain selected areas and this occurs in the same and other specimens in repeated tests. The pattern suggests undulating type of movement with simultaneous inbending in the region of impact and outbending beginning at the border of the area of inbending. In Figure 17 the red lines are those of the internal pattern and the black lines constitute the patterns seen on the external surface of the skull. It is apparent that unbending takes place in the region of the red lines while outbending occurs in the area of black lines. The undulating character

istics of the deformation pattern thus can be visualized. In Figure 19 note that the inbending or red line pattern is of irregular outline, suggesting an asymmetrical area of inbending peripheral to which discrete areas of outbending can be seen. The strain is anteroposteriorward in the parieto-occipital areas of both sides, from side to side anterior to the area of impact and in the squamous portion of the occipital bone. Thus, the outbending of the skull may be in different planes in various regions after a single impact. This is in part governed by buttresses, contiguous thick and thin areas of bone and the shape of the injuring object.

Fig. 12. Posterior parietal blow near the lambdoid suture. In the upper left, cracks extend laterally and toward the base. In the lower left, the internal pattern is shown. Again

the external pattern begins where the internal pattern ends. The right upper and lower photographs show some cracks in the lacquer near the frontozygomatic junction on both sides.

In deceleration blows the pattern seen on the internal surface of the skull is of the same type in almost every instance. One sees a star with cracks in the lacquer arranged radially and extending away from the area of impact. In general, the cracks in the star extend farther posteriorly and anteriorly than superiorly and inferiorly since the radius of curvature in the first instance is much greater and the skull is found to curve much more rapidly in the superior inferior direction. The star pattern suggests an inbending with strains most concentrated in the region of impact. It appears from the pattern and the type of deformation that shear forces act between the two layers

of the skull and may cause a sliding action between the outer and the inner table. If the blow is sufficiently severe and localized an area of actual depression may occur and as the bone fails resulting in depression a tearing apart of the inner and outer tables of the skull may take place. In some cases with depression fragmentation of the bone in the area of deformed bone may be governed by the inbending pattern seen on the internal surface of the skull.

The internal pattern does not disclose a characteristic path of strain in any given direction it rather points to the fact that due to the inbending of bone the strain extends

Fig. 3. Parieto-occipital blow midway between midline and mastoid and on the lambdoid suture. The upper left shows series of cracks extending down toward the base of the skull also seen in the lower photograph. The cracks divide into one group curving medially and another extending forward toward the base. Still other cracks are noted just lateral to the occipital process of the occipital bone. In the upper right photograph, the pattern seen on the internal surface of the skull is shown.

radially from the point of impact only limited by the radius of curvature and peculiar structural characteristics of the skull. In blows not severe enough or sufficiently localized to cause depression or perforation the production of a linear fracture is governed by strains seen on the external surface of the skull. This suggests initiation of the fracture line away from the point of impact. After the crack forms it propagates in both directions, toward

and away from the area of the blow. Its extension toward the area of the center of the impact can be explained by the fact that although the area of indenting on the outer surface of the skull is initially in compression as the bone rebounds tensile strains appear with the maximum values at the center. The propagation of the fracture line to this region of tensile strains is to be expected. The fracture reaches the center and usually does not extend further

Fig. 14. Right occipitoparietal blow 3 inches from the midline and just superior to the lambdoid suture. In the upper left photograph, cracks are seen extending down toward the mastoid bone. In the upper right, a typical star pattern is noted. Superimposition of the internal and external group of cracks makes it evident that the external group start as the internal group end. In the lower figure there are several cracks extending toward the foramen magnum and a few crossing the midline obliquely.

because the tensile strain gradient decreases rapidly from the center outward. In certain positions two lines of fracture may begin on either side of the skull uniting at the point of impact. It is difficult to explain the genesis of linear fracture from the internal star pattern since the propagation of the fracture line would extend in both directions from the center of the area of impact in every case and reach as far as the border of the area of inbending. In some of the specimens studied a linear fracture did occur. This line frequently extended to the area of impact and in no instance was the line seen crossing the region of the blow. If the internal pattern were significant relative to the causation of linear frac-

tures such a separation of bone should have been seen crossing the area of impact and limited to the pattern on the internal surface of the skull. It should be pointed out that the two-layer characteristic of the skull through the greater portion of the vertex suggests that in the inner table a greater degree of deformation without fracture can occur because it is much thinner than the outer table of the skull. It is of course admitted that shear forces occur between the two tables at impact.

Thus far blows with a hammer having a face of one inch in diameter and deceleration blows on a flat steel plate have been studied. With the hammer the area of contact is smaller hence a smaller area of inbending takes

Fig. 5. Midline occipital blow at the lambdoid suture. 1 the upper left, three groups of cracks are noted, 1 laterally one anteriorly. On the internal surface of the skull, in the photograph 1 the upper right, is seen an irregular star which fits in the space between the external group of cracks. 1 the lower photograph, cracks 1 the lacquer extend toward the foramen magnum and lateral to the same (see Fig. 9)

place. With deceleration blows a larger area is contacted with a more extensive indending. However in both groups of experiments the general pattern of tensile strains is the same. More work is contemplated with blows on convex and concave surfaces.

The work with the "stresscoat" points to the following explanation of linear fracture. The area of impact is indented with simultaneous outbending of some of the surrounding area of bone. This outbending is selective and occurs more readily in some places than others. The pattern of cracks in the lacquer resulting from the outbending parallels most fracture lines seen clinically. The "stresscoat" work

suggests that many linear fractures are initiated at a distance from the point of impact extending toward the point of impact and in the opposite direction. Some fractures may appear on either side of the area of impact simultaneously and meet at the point of impact. Two fracture lines may be initiated in different parts of the skull and extend toward the area of impact.

It is recognized that in these studies blows are administered to a single area on the skull, whereas in ordinary deceleration injuries such as in automobile accidents, multiple blows may occur practically simultaneously changing the resultant patterns appreciably. How

Fig. 6.

Fig. 18

Fig. 17

Fig. 19.

Fig. 16. Midfrontal blow with internal pattern shown in red and external pattern in black. Note that inbending about the point of impact is surrounded by an irregular outbending of the skull. The outbending is superoinferiorly in the right forehead region and obliquely superoinferiorly and about at right angles with the first described outbending in the left forehead region.

Fig. 17. The red lines indicate the internal and the black lines the external patterns after a lateral frontal blow, as seen in Figure 4. Note that the outbending of the skull is mainly in the anteroposterior direction. Note also that the internal pattern is more extensive in the anteroposterior direction due to the greater radius of curvature of the skull in this plane.

Fig. 18. Composite representation of internal and external patterns shown in Figure 5. The red, or the internal and the black, or the external, cracks dovetail with each other. Note that after an asymmetrical inbending about the area of impact there are areas of outbending with strains anteroposteriorly on the lateral aspect and from side to side in the pattern posterior to the area of inbending.

Fig. 19. This is a composite representation of the internal and external patterns as seen in Figure 15. Note that the strain is from side to side in the anterior and basal group of black lines, and anteroposteriorly in the lateral group of black lines. Note the irregular bordered internal pattern of red lines that fit in the space left vacant between the outbending patterns on the external surface.

ever the effect of multiple blows can be visualized by the superimposition of patterns obtained from single blows.

CONCLUSIONS

1 Many linear fractures result from out bending of the skull and they are initiated away from the point of impact

2 Many linear fractures are initiated on the outer layer of the skull by tensile (tearing apart) strains.

3 From the position of the area of impact the direction of the resultant fracture line may be surmised

4 From the position of the fracture line the area of impact causing the injury may be surmised

THE STABILITY OF THROMBIN, PENICILLIN OR STREPTOMYCIN, IN THE PRESENCE OF GELATIN SPONGE, OXIDIZED CELLULOSE OR EACH OTHER

JOHN T CORRELL, Ph D., and E. C WISE, MS Kalamazoo Michigan

THERE is an increasing interest in the biologically absorbable matrices such as absorbable gelatin sponge (2) and oxidized cellulose (8 10) Potent concentrates of the blood clotting enzyme thrombin have been used in conjunction with these substances to enhance hemostasis That such surgical adjuncts might also be impregnated with certain of the antibiotics and implanted in wound areas to give desirable local or even prolonged systemic concentrations presents an intriguing possibility

Seegers and Doub have reported that thrombin is destroyed by oxidized cotton within a few minutes due to the acidic nature of the fibers when the cotton was treated with a solution of bicarbonate it lost its destructiveness to thrombin The purpose of this paper is to report investigations concerning the effect of gelatin sponge and oxidized cellulose on solutions of thrombin penicillin or streptomycin also data on the stability of thrombin and penicillin and thrombin and streptomycin when this enzyme is in solution with each antibiotic

THROMBIN IN THE PRESENCE OF GELATIN SPONGE (GELFOAM) OR OXIDIZED CELLULOSE

The bovine thrombin used was prepared in our laboratory essentially according to the method of Astrup and Darling Sufficient powdered thrombin was dissolved in 20 cubic centimeters of distilled water to yield a solution with an initial clotting potency of 500 units per cubic centimeter when assayed with pooled plasma (6) This original solution had a pH of 6.6

A 100 milligram gelatin pad was wet and mixed intimately with 10 cubic centimeters of the above thrombin solution the solution pH then measured 6.0 With the sponge in it the

aliquot was allowed to stand under laboratory conditions and was assayed at intervals for thrombin potency (Table I)

In a similar manner a 100 milligram piece of oxidized gauze was mixed with the remaining 10 cubic centimeters of thrombin solution (pH became 3.7) and intermittent assays for clotting potency obtained as indicated in Table I

The unneutralized oxidized gauze was immediately destructive to the enzyme activity this is in agreement with data previously reported (7) Gelatin sponges were found to have no effect on the thrombin concentration

PENICILLIN IN THE PRESENCE OF GELATIN SPONGE OR OXIDIZED CELLULOSE

For these investigations penicillin (calcium salt) was dissolved in a liter of distilled water to give a solution having 300 micrograms per cubic centimeter with a pH of 6.5 A 200 cubic centimeter aliquot of this was set aside as a control (solution A Table II) All solutions were held under laboratory conditions and penicillin determinations made at stated times by a chemical assay technique (3)

A pad of absorbable gelatin weighing approximately 1 gram was wetted and suspended in a 200 cubic centimeter volume of the mother

TABLE I — EFFECT OF GELATIN SPONGE AND OXIDIZED CELLULOSE ON THROMBIN POTENCY

Time	Gelatin sponge in thrombin solution (Units/c.c.)	Oxidized cellulose in thrombin solution (Units/c.c.)

TABLE II.—EFFECT OF OELATIN SPONGE AND OXIDIZED CELLULOSE ON PENICILLIN POTENCY

Time	A	B	C	D
	Penicillin solution (control) penicillin (micrograms)	Gelatin sponge in penicillin solution penicillin (micrograms)	Oxidized cellulose in penicillin solution penicillin (micrograms)	Penicillin solution buffered to pH penicillin (micrograms)
Initial potency	300	300	300	300
1 hour	300	90		
3 hours	290			
7 hours	270			2

liquor (solution B Table II) pH of this solution became 6.2. Penicillin concentrations were ascertained and recorded (Table II).

To another 200 cubic centimeter portion was introduced a pad of oxidized gauze weighing approximately a gram (solution C Table II). The acidic nature of the gauze lowered the pH of the penicillin solution to 3.1.

Loss of thrombin activity in the presence of oxidized cellulose has been shown (7) to be due to the acidity which cellulosic acid imparts to the solution. With this in mind the final 200 cubic centimeter aliquot of the original penicillin solution was adjusted to a pH of 3.0 (solution D Table II) or to the same acidity as that of the oxidized gauze treated solution and penicillin activity followed.

Typical results for such studies are revealed in Table II. Gelatin sponges were relatively innocuous to the penicillin; there appears to be in the first 2 hours a loss of about 20 per cent of the antibiotic activity with very little subsequent loss throughout the experimental period. The oxidized cellulose destroyed nearly 90 per cent of the total penicillin, with 75 per cent being destroyed in the first 2 hours. Penicillin solutions that had been buffered to an acidity corresponding to that produced by the gauze demonstrated similar loss of potency. This would indicate that the deleterious action of the oxidized cellulose could be ascribed to its inherent acidity.

STREPTOMYCIN IN THE PRESENCE OF OELATIN SPONGE OR OXIDIZED CELLULOSE

For these studies distilled water solutions of streptomycin (sulfate) were so prepared

TABLE III.—EFFECT OF OELATIN SPONGE AND OXIDIZED CELLULOSE ON STREPTOMYCIN POTENCY

Time	A	B	C	D
	Streptomycin solution (control) streptomycin (micrograms)	Gelatin sponge in streptomycin solution streptomycin (micrograms)	Oxidized cellulose in streptomycin solution streptomycin (micrograms)	Streptomycin solution buffered to pH streptomycin (micrograms)
Initial potency	1,000	1,000	1,000	1,000
1 hour	10,700	1,000	10,000	10,000
3 hours	1,000	1,000	10,000	1,000
7 days	700	1,000	10,000	1,000

that each cubic centimeter contained about 11,000 micrograms of pure streptomycin base. All solutions were kept under laboratory conditions throughout the entire period of study. Streptomycin assays were made as described by the Food and Drug Administration (5).

As listed in Table III A was a water solution (pH = 5.5) of the drug only as a control. B (pH = 5.4) was 35 cubic centimeters of streptomycin solution to which a 200 milligram sponge of absorbable gelatin was added. C (pH = 2.6) was the same volume of streptomycin solution with a 200 milligram piece of oxidized cellulose in it. D was the antibiotic solution alone buffered to a pH of 3.0.

Streptomycin in solution was stable (Table III) under all the conditions to which it was subjected in these studies for as long as 10 days.

THROMBIN AND PENICILLIN ACTIVITIES WHEN THE TWO ARE IN MUTUAL SOLUTION

Thrombin is used clinically often in conjunction with an absorbable matrix to enhance or assure hemostasis. The desirability of using bacteriostatic substances in wound treatment suggested that perhaps when thrombin was employed to stay hemorrhage it would often be rational to put the clotting enzyme in solution with the bacteriostatic agent of choice to permit simultaneous application. Information was needed as to the compatibility of thrombin and such substances. The study presented here and the following one are the results of our experiences with two of the antibiotics.

TABLE IV—STABILITY OF THROMBIN AND PENICILLIN WHEN IN MUTUAL SOLUTION

Time	Thrombin (units/c.)	Penicillin (units/c.c.)
Initial potency	200	1,000
1 hour	200	60
1 hour	75	0.20
3 hours	50	0.60
7 hours	20	0.20

Thrombin and penicillin materials used were the same as identified in the previous studies as was also the technique for thrombin assay. Penicillin was determined by the cylinder plate method (4) with dilutions made in buffer of pH = 6.0.

A distilled water solution of penicillin was prepared to have a concentration of 1,000 Oxford units per cubic centimeter. Powdered thrombin was dissolved in this solution to give a clotting potency of 200 units per cubic centimeter. The mixture was held at room temperature and assayed as indicated (Table IV) for each constituent.

Within the errors of the assay techniques neither thrombin nor penicillin showed any loss of potency when in mutual water solution for over 7 hours.

THROMBIN AND STREPTOMYCIN ACTIVITIES WHEN THE TWO ARE IN MUTUAL SOLUTION

Experiments similar to those reported for penicillin have been carried out with streptomycin.

Streptomycin (sulfate) was dissolved in distilled water to a concentration of 11,000 micrograms per cubic centimeter. This solution was used to reconstitute powdered thrombin to a clotting potency of 500 units per cubic centimeter. The mixture was held at room

TABLE V—STABILITY OF THROMBIN AND STREPTOMYCIN WHEN IN MUTUAL SOLUTION

Time	Thrombin (units/c.c.)	Streptomycin (micrograms/c.c.)
Initial potency	500	1,000
1 hour	500	—
1 hour	500	0.350
3 hours	500	—
7 hours	500	—
7 hours	200	0.00

temperature and assayed for each entity by methods which have been mentioned (5, 6).

Both the thrombin and streptomycin (Table V) retained their initial potency when in solution with each other.

SUMMARY

The enzyme, thrombin and the antibiotic, penicillin were both rapidly destroyed by oxidized cellulose. This is apparently due to the lowering of the pH of such solutions by the gauze, for thrombin or penicillin were also unstable in solutions buffered to a pH corresponding to that produced by pieces of oxidized cellulose.

Thrombin or penicillin showed no loss of potency from solutions in which absorbable gelatin sponges were suspended. The gelatin sponges did not significantly alter the inherent pH of the solutions.

Streptomycin was stable in the presence of either gelatin sponge or oxidized cellulose.

When powdered thrombin concentrate (bovine) was reconstituted with an aqueous solution of penicillin or streptomycin all constituents were compatible as evidenced by no loss of enzymatic or antibiotic potency.

The possible combinations for studies of this type are numerous particularly as concerns the use of the absorbable matrices with aqueous solutions of various substances. Some of these are being investigated. Preliminary data indicate that ascorbic acid which has been reported (9) to be of interest in wound healing shows little deterioration in the presence of gelatin sponge or oxidized cellulose.

SUBPERITONEAL HEMORRHAGE FROM VITAMIN C DEFICIENCY SIMULATING ACUTE SURGICAL ABDOMINAL CONDITIONS

LAURENCE F HINES M.D. Chicago, Illinois

THE frequency of atypical and even asymptomatic vitamin deficiencies is now well established. Routine vitamin C administration in postoperative states is based on our knowledge that scurvy may exist with or without characteristic symptoms, physical signs or roentgenologic evidence. The typical symptoms attributed to classical scurvy are hemorrhages, anemia, swollen and bleeding gums and bone changes; however, these are not often encountered.

The diagnosis in the atypical or subclinical case is made by laboratory methods, signs of capillary fragility, and a careful analysis of food intake together with factors capable of inhibiting absorption, such as decreased utilization in hepatic disease, the increased secretion in lactation, the increased destruction by alkalis, and the increased requirements of metabolic disorders.¹

Hemorrhage is one of the most significant and characteristic features of scurvy. This may be obvious as seen in bleeding gums, purpuric lesions or hematuria. It may be less obvious if the bleeding is in the muscle, joint or internal viscous. In the cases here reported the hemorrhages were subperitoneal and the manifestations were similar to those of acute surgical abdominal diseases. In various surgical monographs little or no consideration is given to the possibility of surgical mistakes on this basis, although cases of cryptogenic spontaneous hemorrhage of the abdominal walls have been reported.

CASE 1. R.E.F., a 17 year old male whose previous health had been good, was admitted to St. Joseph Hospital, November 1, 1945, about 5 hours after having been kicked in the abdomen by a teammate during a high school football scrimmage. Momentarily

he was stunned by the injury and was excused from practice. Thirty minutes later he vomited, and pain in the epigastrium increased steadily until 3 hours later it was described as unbearable. Examination revealed marked tenderness and rigidity in the upper half of the abdomen. The temperature reading showed 99 degrees F. There were no findings in the chest or upper respiratory tract. A blood examination showed 15,000 leucocytes, 92 per cent polymorphonuclear hemoglobin 14.0 grams, and the erythrocyte count was 5,050,000. An x-ray examination of the abdomen revealed no free air or ladderling of the intestines.

A laparotomy was performed by Dr. Bertram Fitzgerald 6 hours after the onset because rupture of an abdominal viscus was suspected. When the peritoneum was opened there was no air or excessive fluid present. The liver and spleen were normal. When the common mesentery was exposed, an enormous number of ecchymotic and petechial hemorrhages covered almost the entire mesentery. A few were scattered over the anterior surfaces of the cecum, ileum, and jejunum. No additional pathology was discovered and, after all viscera had been inspected for perforation, the abdomen was closed.

Partial atelectasis of the right lung on the second postoperative day produced some dyspnea and slight fever (102 degrees F as the maximum) but otherwise ran an uneventful course.

On the day following surgery blood studies revealed prothrombin time 26 seconds (normal 21 seconds), clotting time 3 1/2 minutes, bleeding time, 1 to 2 minutes, platelet count about 300,000 per cubic millimeter, ascorbic acid level on whole blood plasma, 0.3 milligram.

A capillary fragility test with the blood pressure at 80 millimeters of mercury for 5 minutes showed numerous petechia. Further questioning revealed that the patient's diet was inadequate. He rarely ate raw fruit, vegetables, salads, or fruit juices. He ate considerable amount of sweet foods and moderate amounts of meat and milk.

The postoperative care consisted of an appropriate diet and 500 milligrams of ascorbic acid parenterally daily. At the end of 10 days he was discharged in good health with the wound well healed.

CASE 2. H.M., a 45 year old white male, entered St. Joseph Hospital, May 21, 1946 complaining of a dull pain in the right lower quadrant of his abdomen which had developed suddenly 4 days previous to admission. There was no nausea or vomiting. A

From Departments of Medicine of St. Joseph Hospital and Northwestern University Medical School.
Cajal D. *Id. J. Am. M. Ass.* 1946, 131: 318.

Figs. 1 and 2 Photomicrographs of tissue removed in Case 2. Note hemorrhage between the fat cells and marked hyperemia of blood vessels.

physician in a Boston hotel diagnosed the case as acute appendicitis but the patient refused surgery and returned to his home in Chicago.

Physical examination revealed an apprehensive man whose blood pressure readings were 160 systolic and 90 diastolic, tenderness rigidity and a suggestion of a mass in the right lower quadrant near Mc Burney's point temperature 99 degrees F and a leucocyte count of 11,350. A diagnosis of appendicitis was made. When the peritoneum was exposed, a thick indurated mass was encountered. This was the greater omentum adherent to the anterior parietal peritoneum. The parietal subserosa at the site was extensively infiltrated with hemorrhage and the omentum was thick and purple. A cut section through the removed omental mass revealed firm fatty tissue 8 by 3 by 1 centimeter with a large area of hemorrhage about 4 centimeters across and scattered small petechiae.

Microscopic sections revealed fatty tissue with hemorrhage between fat cells and marked hyperemia of the blood vessels (Figs. 1 and 2).

Studies the day after surgery revealed the ascorbic acid level 0.6 normal bleeding time, normal clotting time, normal platelet count, and normal prothrombin time. The capillary fragility test was strongly positive.

Subsequent questioning revealed that he took from four to ten drinks of whiskey each day and seldom ate citrus fruits or vegetables.

CASE 3 Mrs. K.L., a 30 year old white woman was admitted to St. Joseph Hospital August 12, 1946 complaining of severe abdominal pain which began suddenly about 5 hours previous to admission and was soon followed by vomiting. Physical examination revealed extreme tenderness and board-like rigidity of the abdomen with only occasional peristaltic sounds. Bowel obstruction or perforation of the viscus was suspected, but since ordinary percussion

of the chest and palpation of the muscles of the back and extremities revealed almost as much tenderness as was present in the abdomen and because of the lack of leucocytosis (8000) and fever surgical exploration was postponed.

Twenty four hours later carpopedal spasm with a positive Trousseau's sign and a positive Chvostek's sign was demonstrated and caused us to interpret the muscle pain as a spasm of tetany. Later the husband revealed a long history of alcoholism and a recent debauch in which no food had been taken for several days.

Blood findings fatty turbid serum nonprotein nitrogen 29 milligrams glucose 106 milligrams chlorides 510 vitamin C level, 0.28 inorganic phosphorus 1.8 calcium 6.5 amylase 112 per cent total protein 5.4 with 3.3 albumin and 2.1 globulin cholesterol 144. The low vitamin C level, low calcium low phosphorus low total proteins and the presence of fatty serum was interpreted as evidence of nutritional and vitamin deficiency. Intravenous calcium quickly controlled the muscle pain and spasm, and on a high protein regimen (supplemented by plasma) high vitamins large doses of vitamin C parenterally together with vitamin B complex, and liver extract, she improved promptly and left the hospital with normal blood findings.

SUMMARY

Three cases with symptoms pointing to an acute surgical disease of the abdomen showed laboratory evidence and clinical signs of scurvy. Two patients were subjected to surgery and hemorrhage was shown to be the basis of the peritoneal irritation.

The third patient not subjected to surgery had tetany as well as scurvy. The tetanic

spasms of the abdominal muscles probably accounted in part for the picture of an acute surgical condition. However in this case hemorrhage from scurvy may also have been present.

All the patients gave a history of a diet deficient in vitamin C. Two of the patients were discovered to be alcoholics while trauma to the abdomen was the aggravating factor in one case.

CONCLUSION

In the clinical diagnosis of acute surgical diseases of the abdomen spontaneous hemorrhages from nutritional deficiency or scurvy should be considered. Subclinical scurvy is recognized by consideration of the diet, by consideration of factors capable of inhibiting absorption of vitamin C by physical signs of scurvy by increased capillary fragility and by determination of vitamin C levels in the blood.

A SIMPLE AND ASEPTIC METHOD OF ILEOCOLOSTOMY

Dr J TEN KATE, The Hague Holland

IN shortcircuiting by lateral anastomosis between a proximal and a distal loop of intestine the chief concern is always the prevention of contamination of the operative field. It is very difficult after the intestine is opened to include the mucosa of the colon in the suture in such a manner as to prevent completely contamination of the operative field. Fortunately, with the use of the newer antibiotics the danger of contamination is much less than formerly. Nevertheless in patients debilitated by obstruction and intoxication serious infection may ensue. In addition the introduction of drains which many surgeons consider necessary in contaminated cases promotes a dehiscence of the suture line. For this reason surgeons try by one means or another to carry out aseptic anastomoses. The clamp and the coagulation methods are especially well known. When the clamp method is used (Rankin Stone) the suture is carried out over a specially constructed clamp which is removed at the last moment. Thus the intes-

tine is open only for a few seconds and at one place. According to Rankin in not one of his patients did leakage occur at this stage. When the coagulation method is used the mucosa of the intestine is not opened but is thoroughly coagulated. As soon as the coagulated mucosa sloughs off an open communication between the anastomosed loops is thus established. The difficulty with the coagulation method is to estimate the time necessary to assure that the sloughing off process is complete. We know of one case in which the ileus continued after this coagulation method had been used and death resulted.

Following is a description of a simple method which my former chief the late Dr Schoemaker briefly mentioned in an address on colon surgery before the meeting of the *Société internationale de Chirurgie* at Cairo in 1935 and which was named by his assistants the 'bird-cage' method. The advantage of this method is that an open communication is established immediately between the loops without the use of any specially constructed instrument. We have used the method in several cases and healing of the wound has always

D. Ten Kate was formerly first assistant of the late Dr Jan Schoemaker.

Fig. 3. Suture of the posterior seromuscular flaps.

Fig. 4. Suture of the anterior seromuscular flaps with long threads the center part of which is elevated over blunt hook.

progressed without complications and without drainage

TECHNIQUE

The two segments to be joined are placed side by side for a certain distance, and a posterior (continuous) seroserosal suture is applied. The corner threads are fixed in a hemostat (omitted in Fig. 1). The intestinal wall is divided with a small extremely sharp knife down to the mucosa so that a sufficient oval of the mucosa lies bare. A second (continuous or interrupted) suture passes through the pos-

terior seromuscular flaps of both segments and is tied and cut short at once (Fig. 3).

The loops are now joined on the posterior side by two sutures, one seroserosal and one seromuscular. Long interrupted sutures are placed through both anterior seromuscular flaps. The threads are all elevated and collected, midway over a blunt hook or if need be, a finger of the assistant while both ends are held separately in hemostats (Fig. 4). When all the sutures have been inserted, the hemostats are replaced on each side by a strong intestinal

Fig. 5 Incision of the mucosa of both loops with a diathermy knife.

clamp (Fig 5) If the intestine is full the segments may be milked empty and blocked off by applying clamps across the gut near the anastomosis. When the intestine is not unduly distended the application of clamps can be dispensed with in most cases. While one assistant takes an intestinal clamp in each hand and pulls the threads taut and a second assist

ant or the surgical nurse elevates the center of the threads with a blunt hook, the operator divides the mucosa on both sides with a diathermy knife (Fig 5). The second assistant removes the blunt hook and the first closes the anastomosis by traction in a vertical direction (Fig 6). With good assistants the whole procedure takes but a few seconds.

Fig. 8. left. Anterior sero-serosal uterine

Fig. 9. Anastomosis finished

Sometimes the incised mucosa may bleed considerably but that does not necessitate the ligation of the individual vessels for such a procedure would destroy the relative asepsis of this method. Although we have sometimes had copious diffuse bleeding from the incised mucosa we have never had serious complications from such bleeding. Besides our experience with the Schoemaker closed method of end-to-end union of intestinal segments without suture of the mucosa had convinced us of the harmlessness of mucosal bleeding.

Precaution should be taken also to avoid dividing the sutures with the diathermy knife therefore it is recommended that a relatively broad hook be used to hold the sutures so that access to the mucosa is facilitated.

While the assistant keeps the suture threads taut in a vertical direction the operator cuts the threads one by one just under the clamps and ties them (Fig. 7). When the tying of all these sutures has been completed then an anterior continuous sero-serosal suture is applied and the anastomosis is finished (Figs. 8 and 9).

To prevent the formation of a diaphragm by agglutination of the nonsutured mucosa layers (which we found once as the cause of death in a case of obstruction after a circular resection) it is advisable after the anastomosis is finished to introduce the thumb and index finger on either side to break up any possible agglutination and to be certain that continuity has been restored.

LATE RESULTS OF URETEROENTEROSTOMY

GEORGE GILBERT SMITH M.D. F.A.C.S., Providence Rhode Island

ANASTOMOSIS of the ureters to the sigmoid is a procedure which could be of great value in urology if we could be reasonably sure that the results over a period of years would be satisfactory. This study is presented with the hope that it will shed some light upon this problem.

During the past 17 years—from 1930 to 1946 inclusive—the writer has done this operation in 66 patients. 50 of these had both ureters transplanted in 16 only one ureter was so treated. The ureter which was not transplanted to the bowel was ligated in 6 transplanted to the skin in 8 not operated upon in 2. This makes a total of 116 ureters transplanted to the sigmoid.

The indications for ureteroenterostomy must be considered because the prognosis is much more favorable in some types of cases than in others. For example, the younger the patient the better the outlook. Individuals with cancer are generally in the older groups and frequently their strength and their resistance to infection have been depleted. Some undoubtedly have a smoldering pyelonephritis unrecognized before operation which later becomes active.

In the series of patients here presented the reason for ureteroenterostomy was radium burn of the bladder in 1 urinary incontinence in 2 submucous fibrosis in 4 exstrophy of the bladder in 6 vesicovaginal fistula in 6 and cancer of the bladder or of the bladder and urethra in 47. The radium burn of the bladder and one of the vesicovaginal fistulas were secondary to radiation treatment of cervical cancer. It is I trust unnecessary to say that in all of these patients with the exception of those with malignancy no solution of their difficulties other than transplantation of the ureters could be found.

The technique which was used in all but the last 6 cases was that known as Coffey One (1). This consists in severing the ureter 3 or 4

centimeters above the bladder and embedding the proximal segment in a trough in the wall of the sigmoid which has been made by dividing the serous and muscular coats of the latter for a distance of 4 centimeters. The floor of this trough is the intact mucosa of the bowel. A small incision through the mucosa is made at the lower end of the trough the end of the proximal ureteral segment is drawn into the lumen of the bowel by a double suture both ends of which are brought out through the intestinal wall 2 centimeters below the point of entrance of the ureter and there tied. The edges of the divided muscularis and serosa are then sutured over the ureter. The anastomosis can be done intraperitoneally or extraperitoneally. Both methods were used in this series neither appeared superior to the other.

In the last 6 cases implantation of the ureter in the trough was carried out without opening the lumen of the bowel and without severing the ureter. At the second operation approximately 2 weeks later the ureter was divided 2 centimeters below its emergence from the trough and the proximal end was then led into the lumen of the bowel as in the Coffey One technique. The principle of embedding the ureter in the intestinal wall and allowing it to become healed in the canal before the lumen of the bowel or of the ureter was opened (Coffey Three) (2) was first advocated by Coffey. It has been employed by Higgins (3) who as well as Coffey produced a fistula between the ureter and the bowel either by a constricting stitch or by electrocoagulation. Jewett has varied this technique by producing the fistula by means of an electrosurgical incision made by a device introduced through the proximal end of the ureter which had been divided below the point of emergence. The method followed by the writer and outlined above was first described by Winsbury White; it was also used by Nesbit.

The introduction of the sulfa drugs and the antibiotics has been a great factor in preventing the calamities which sometimes attended

Fig. 1. Excretory urogram years after bilateral ureteroenterostomy for submucous fibrosis. Nonprotein nitrogen 70 milligrams per cent.

such operations before these aids to intestinal antisepsis were known. These agents have also been helpful in preventing the development of pyelonephritis during the postoperative period. Experience has taught us also that deep x ray therapy to the pelvis, by causing fibrosis of the lower ureters, is sometimes responsible for sloughing of the transplanted ureter.

Of the 66 patients operated upon 12 (18+%) died in the hospital. Autopsies were secured in all but one. Ten of these were operated upon for cancer of the bladder, 2 for irradiation necrosis of the bladder following radium and x ray treatment of cancer of the cervix. The causes of death were faulty healing of the anastomosis in 3, sepsis in 2, pyelonephritis in 2, embolism of the femoral artery in 1, thrombosis of the iliac vein, inferior vena cava and left renal vein in 1, streptococcus infection following removal of a nonfunctioning kidney

Fig. 2. Ureteroenterostomy for exstrophy of bladder in 1930; left nephrectomy for stone in 1935; excretory urogram in 1944. Nonprotein nitrogen 43 milligrams per cent.

in 1. No cause was found in 1 coronary thrombosis in 1.

Seven of the above 12 patients had their bladders removed, 32 who had had cystectomy because of cancer and 5 because of exstrophy were discharged from the hospital.

Of the 54 patients who left the hospital alive, 8 died of renal failure, 5 in 1 year or less, 3 between 1 and 2 years. Four others had skin ureterostomies, 3 within 1 year, one 3 years after ureteroenterostomy. At least 4 of those who died should have had their kidneys drained. It is probable that several of these patients would now be alive if the ureters, or even if one ureter had been brought out to the skin. Such a patient was operated upon in September 1945. Left ureteroenterostomy was done, the right ureter ligated and the bladder removed 2 weeks later. Three weeks after that, the right kidney was removed as it was functionless. The patient made a good recovery and

went South. In May 1946 he returned and was seen by my associate, Dr Leadbetter during my absence. He found that the left kidney was not functioning well and advised ureterostomy. The patient did not follow this advice; he continued to fail and at the last moment, left nephrostomy was done. He died 4 months after being advised to have a ureterostomy. Autopsy showed a septic kidney; no cancer was found.

Fourteen patients died from recurrence of their bladder cancer. In 8 of these patients renal function appeared to be satisfactory.

Of the patients who are still living, 3 have unsatisfactory kidney function. A woman 54 years of age was operated upon in 1934 because of a vesicovaginal fistula which had resisted a number of attempts to repair it. In 1938 her left kidney was removed because of calculous pyonephrosis. Now 9 years later her right kidney is enlarged; her nonprotein nitrogen is 91 milligrams per cent and her blood pressure is usually about 215/120. She is almost bedridden.

Another woman, aged 59 in 1934, had her ureters transplanted because of a severe submucous fibrosis. She had been well until lately but now is in a hospital with nonprotein nitrogen of 70 milligrams per cent. Her intravenous pyelograms made 3 months ago showed slight dilatation although both kidneys excreted diodrast (Fig. 1). She is now 74 and probably would not wish to have the ureters brought out to the skin.

A third patient, a young man of 19, had bilateral ureteroenterostomy for exstrophy of the bladder in 1930. In 1935 a left nephrectomy was done for calculous pyelonephritis. He came to the office a few weeks ago at my request as he had not been seen since 1941. At that time an intravenous pyelogram had shown considerable dilatation of the calices, pelvis and upper ureter on the right; his nonprotein nitrogen was 43 milligrams per cent (Fig. 2). At this last visit his nonprotein nitrogen had risen to 49 milligrams per cent and his blood pressure was 0/140. An intravenous pyelogram shows poor excretion of dye but much less dilatation (Fig. 3). In spite of this he is working as an accountant and considers himself in good health. It is doubtful

Fig. 3. Excretory urogram taken in 1947 of patient whose 1941 urogram is shown in Figure 2. Nonprotein nitrogen 49 milligrams per cent. Blood pressure 220/140.

whether surgical drainage of the kidney should be advised.

Some surgeons prefer nephrostomy to ureterostomy. Our experience leads us to favor the latter because the operation is less severe and because the location of the drainage tube is more convenient for the patient. Neither method is ideal. In a series of 22 skin ureterostomies studied a few years ago there were 4 deaths from pyelonephritis occurring from 1 to 10 years after operation.

Among the 66 patients in the present series there are living in addition to the 6 patients whose ureters are not functioning satisfactorily, 18 whose renal function is reasonably adequate. The time elapsed since operation is: 1 year or less in 2; 1 to 2 years in 2; 2 to 3 years in 3; 3 to 4 years in 1; 4 to 5 years in 1; 6 to 7 years in 2; 8 to 9 years in 4; 10 to 11 years in 1; 11 to 12 years in 1; 12 to 13 years in 1.

One of these patients, a girl of 18 who was operated upon for exstrophy in 1936, delivered herself of a living child 3 years ago. She had no renal complications during or after her pregnancy although her left kidney showed diminished function in 1939. Her nonprotein nitrogen now is 31 milligrams per cent. Another girl, age 30 at the time of operation, had ureteroenterostomy for exstrophy of the bladder in 1936. Ten days after her left ureter was transplanted she developed pyelonephritis.

Fig. 4. Excretory urogram in boy 1 year after ureterocentrostomy and cystostomy for bladder

Fig. 5. Excretory urogram of patient in Figure 4 15 years after operation. Note improved renal drainage.

the ureter was exposed and found to be indurated and acutely inflamed. It was opened with the escape of thick pus and a catheter was passed downward into the bowel where it was left for 10 days. The urine was drained by a temporary nephrostomy. The excretory urograms in 1943 showed slight dilatation of

the right pelvis and ureter very little dilatation and good function on the left. Her non protein nitrogen was 16 milligrams per cent.

Six of the patients now alive had cystectomy for cancer 5 of these have gone less than 3 years one is well 7 years after operation One has recurrence in the anterior vaginal wall

TABLE I.—RESULTS ACCORDING TO DIAGNOSIS

one is now convalescent one at the end of 2 years and 2 at the end of 3 years are in excellent health. Another is alive after 2 years but has severe cardiac disease and is not in good health.

Tabulation of the patients according to diagnosis shows the marked difference in results between the patients in whom malignancy was not a factor and those in whom (Table I) the ureteral transplantation was done because of cancer of the bladder or because of the results of radiation for cancer of the cervix. The 14 who died of recurrence added to the mortality in the malignant group. Fourteen others—29 per cent of the malignant group—died within 3 years of operation from renal complications or from causes which could not be determined. Nine (18%) of this group with cancer are now living, 3 with ureterostomies.

In contrast to the above results among the 71 patients in the nonmalignant group one

died of liver disease, one of pyelonephritis, 15 are living. Figures 4 and 5 show an excellent result following ureteroenterostomy in a child.

Of the total patients, 24 in number who are living anywhere from a few months to 17 years since operation, 13 have been found by recent examination or have been stated by their doctors to have satisfactory renal function. Four others have had bilateral ureterostomies. Four are known to have poor function in one or in both kidneys. Three have not been checked recently but were well at last report.

In several of the patients with inadequate renal function it has been found that there is very little dilatation of the renal pelvis now although there had been considerable in the past. In one such case a nephrostomy was done; the kidney was contracted and scarred, the pelvis and upper ureter not at all dilated. Nephrostomy brought about marked improvement in the patient's condition within a few

Fig. 8. Twenty minute excretory program after the completion of the operative procedure of bilateral ureterostomy

Fig. 9. Twenty minute excretory program 3 years after operation. Nonprotein nitrogen 47 milligrams per cent. Same case as in Figure 8

days the elevated nonprotein nitrogen became normal. Bilateral skin ureterostomy was done a few months later with excellent results. She has gained 35 pounds in weight, and feels better than she has felt in the past 12 years. Her nonprotein nitrogen however is now 48 milligrams per cent.

Review of this series of patients shows no immediate mortality in the nonmalignant cases, and in those with malignancy a hospital mortality of 18 per cent. This is not excessive in view of the prognosis without radical operation. The high incidence of death from recurrence (about 30%) argues for greater conservatism in the selection of cases for total cystectomy. It would have been better in certain of these patients with single infiltrating tumors to have electrocoagulated the tumor thoroughly through the open bladder. The cases best adapted to cystectomy are those patients with

multiple, persistently recurring tumors of the lower grades of malignancy.

The real problem has to do with the preservation over a long period of years, of the renal function. We do not know why some kidneys after ureteral transplantation remain normal for years, while others cease to function. Not infrequently one kidney will remain healthy although its fellow atrophies.

The two agents chiefly concerned in this problem are obstruction and infection. Unquestionably there is some factor involved in the transplantation which is responsible for the poor result, but it is usually unrecognized by the surgeon at the time of operation. What is needed is a foolproof method of transplantation which if done with reasonable skill, will guarantee results.

The method of transplanting the ureters in continuity described earlier in this paper may

possibly be the answer. The logic behind this technique lies in the fact that the ureter becomes healed in the intestinal wall before either lumen is opened. The likelihood of the ureter becoming encased in a plastic layer of inflammatory tissue is materially lessened. At the second operation, before implanting the severed ureter in the intestinal lumen, bougies may be passed up the ureter to demonstrate its patency.

The second stage may be difficult because of adhesions or inaccessibility of the anastomosis but these factors can be foreseen and to a large degree prevented. The transverse incision for example gives much better access to the pelvic walls and if the anastomosis is not made too low in the sigmoid it will be more accessible. Five of the 6 cases in which this method was used by the writer have done well so far as the ureteroenterostomy was concerned. These 5 had cancer of the bladder. The sixth patient died in 6 months, probably from pyelonephritis; he was operated on for incontinence (Fig. 6). Two have died: one at 5 months from coronary thrombosis, one at 9 months from recurrence of the carcinoma (Fig. 7). Both are reported to have had no urinary difficulty. Another was operated on only 3 months ago; the right ureter was transplanted by this method, the left by Coffey's one technique and it must be admitted that there is as much dilatation on the right as on the left. Another returned to the hospital 6 months after operation with fever and right upper quadrant pain; he was in acute cardiac decompensation, the nonprotein nitrogen was 158 milligrams per cent but fell rapidly to 52 milligrams per cent. His doctor 1½ years later said the patient had had no trouble with his kidneys since then.

The remaining patient operated on over 3 years ago was seen recently. Her nonprotein nitrogen was 47 but intravenous pyelograms showed a very satisfactory result. She feels perfectly well (Figs. 8 and 9).

In conclusion, let me say again that ureteroenterostomy is a procedure of the greatest value. The results in patients with cancer

have been far from satisfactory, of 49 patients only 9 (18%) have survived and only 1 of these has gone over 3 years. In nonmalignant cases the results have been much better but the late development of renal failure in some patients has been discouraging. It is to be hoped that new and better techniques for the anastomosis of the ureter to the bowel will be forthcoming. In the meantime, we must stand ready to establish better drainage by ureterosomy or nephrostomy for those kidneys which are not functioning satisfactorily after ureteroenterostomy.

SUMMARY

1. The results of ureteroenterostomy in 66 patients operated upon in the period 1930 to 1946 are tabulated.

2. In 47 patients with cancer of the bladder and 2 with treated cancer of the cervix there were 12 hospital deaths and 14 deaths from recurrence of the cancer. Eight died, after discharge from the hospital, of pyelonephritis.

3. In 17 patients operated upon for nonmalignant conditions there were no hospital deaths and only 1 death later from pyelonephritis.

4. Of 24 patients now alive, 17 have satisfactory renal function, 3 show signs of renal failure, 4 have required skin ureterostomies.

5. In at least 4 of the patients who died of pyelonephritis renal drainage by ureterosomy or nephrostomy would probably have materially prolonged life.

6. In patients who have had ureteroenterostomy, the renal function should be followed by determination of nonprotein nitrogen and by excretory urograms at least once a year. If the kidneys show evidence of progressive failure nephrostomy or ureterosomy should be done.

SURGERY OF THE ENDOCRINE GLANDS

OUR surgical experience with lesions producing metabolic disturbances has greatly increased the past few decades. In addition extensive investigative work has been carried out in this field of disease. The knowledge obtained from these sources has enabled us better to understand this group of diseases. In some of them we have developed a method of clinical relief in others unfortunately we have learned that these metabolic syndromes are not as simple as we at first thought them to be. Most lesions that produce metabolic disturbances are operated upon by the general surgeon. The neurosurgeon, gynecologist or urologist, however, treat some of these lesions, such as tumors of the pituitary, ovaries, or adrenal glands.

The diagnosis and treatment of thyrotoxicosis have improved so much that the mortality and morbidity occurring in its management

have been reduced to a minimum. In 1943 Aastwood introduced thiouracil for the treatment of this disease. As happens with most new therapeutic agents it was received with a wave of great enthusiasm. This enthusiasm diminished considerably when we learned that the number of permanent remissions obtained in treating thyrotoxicosis was not as great as was at first anticipated. It has been tried in recurrent cases following thyroidectomy and the results are not too encouraging. In the Presbyterian Hospital in New York it was used in twenty-five recurrent cases; fifteen showed recurrence of symptoms in from one to six months after discontinuation of the drug—most of them in three months. The enthusiasm was further reduced when agranulocytosis, a complication due to the toxicity of the drug, was reported in some cases. Frequent blood counts should be included in the routine when patients are taking this drug to detect any early evidence of anemia or agranulocytosis. This complication is rarely fatal when recognized early; the drug discontinued and treatment instituted; nevertheless, Beler, Waltes and Sturgis recently reported an analysis of 10 fatal cases which they collected from the literature and by personal communication. Microscopical studies show that thiouracil produces hyperplasia and increased vascularity of the gland. This has been responsible for the surgeon encountering more hemorrhage in operations performed upon patients prepared by this drug preoperatively. This factor has led many surgeons to feel that thiouracil has a distinct disadvantage over iodine and has little or no advantage in the preoperative preparation in cases of mild or moderate toxicity. Many feel however that thiouracil has won

its niche in the preoperative preparation of cases of severe thyrotoxicosis. In these cases many clinicians use it until the symptoms have improved appreciably and the basal metabolic rate has been reduced to about half of its original reading. Then the drug is discontinued and iodine substituted to complete the preoperative preparation. Under this therapeutic regimen the hyperplasia and vascularity are reduced, resulting in the reduction of hemorrhage encountered in thyroidectomy. Thiouracil is of value in the preoperative preparation of patients who cannot tolerate iodine in severe thyrocardiacs and in patients who obviously would not stand or who refuse operation. One of the related drugs such as propylthiouracil, may prove less toxic and our deductions changed accordingly.

Apathetic thyrotoxicosis as described by Lahey in 1931 merits consideration. Since this contribution we have noted an increasing number of this type of thyrotoxicosis. Lahey not only cited the high operative mortality in this group but also pointed out that if this condition is not recognized it may be responsible for the death of a patient operated upon for some other surgical condition.

As in other diseases we now realize that liver damage plays a very significant part in fatalities from thyrotoxicosis. Two types of liver pathology have been described in this disease. Several liver function tests have been used to determine clinically the degree of liver damage. It has been advocated that liver damage plays such an important part in thyroid crises that we should call them liver crises. Chesky reported favorable results in a series of cases of advanced liver damage in which he added intravenous glucose with insulin, liver concentrate, and glycine to his routine treatment.

Surgery performed upon the diabetic is one of the most interesting of surgical fields. It

was one of the first types of surgery in which we learned that the combined management of the internist and surgeon was essential both to progress and the proper care of the patient. Though our mortality and operative results have improved tremendously, there is still room for improvement in the management of emergency cases. An important accomplishment in this field is the recognition of the fact that early diabetic acidosis has a group of symptoms identical with that of many acute abdominal conditions. We no longer wait until the patient exhibits drowsiness or coma before we think of acidosis. The recognition of this hazardous complication in its earlier stage has diminished the number of patients operated upon in its presence and thereby lowered our operative mortality.

Refrigeration in the management of cases of diabetic gangrene has proved to be of definite value. We first used this procedure only in patients who were very toxic, the result of absorption from the gangrenous process. Today refrigeration is a routine preoperative measure if the gangrene is complicated by gross infection. In operations of election we can now properly prepare the diabetic so that he is as good an operative risk as is the condition of his cardiovascular system.

The number of cases treated for hypernatulinism is very slowly increasing. Unfortunately no one surgeon has the opportunity of treating or operating upon many patients with this condition. The triad of symptoms characteristic of hypernatulinism have been well recognized. They are (1) attacks of hypoglycemia coming on during the fasting or overfatigued state, (2) associated blood sugar readings of 50 millimeters per 100 cubic centimeters or less during the attacks, and (3) relief of the shock promptly following the ingestion of glucose. Some very gratifying results have been reported when a tumor of the

islands of Langerhans has been found and removed at operation. A few cases of extra pancreatic islet tumors appear in the literature. These cases show the necessity of exploring the entire pancreas, duodenum, and other neighboring tissues before we consider our exploration for tumor complete. The real problem is the case in which no tumor is found. We have called these the functional type, and partial to subtotal pancreatectomies have been performed in an effort to obtain a cure. Follow up studies in these cases have not been as encouraging as we at first hoped they would be.

A fairly well established routine has developed in the diagnosis and treatment of hyperparathyroidism. The infrequency with which this lesion is encountered has prohibited too great progress in this field. The incidence is substantially higher in those clinics where hyperparathyroidism is carefully sought among patients presenting themselves because of renal calculi. It is important that hyperparathyroidism be recognized even in such cases in which characteristic skeletal disease is absent because of the possibility of disastrous injury to kidney function. Just as primary hyperparathyroidism can induce serious kidney disease, serious primary kidney disease may result in a compensatory secondary hyperparathyroidism. The treatment of primary hyperparathyroidism is surgical; that of secondary hyperparathyroidism is not.

Tumors of the adrenal gland present a very complex picture. Occasionally in the course of a sympathectomy for hypertension a tumor is found in this gland which has produced no symptoms. The surgeon should be aware of the fact that a common complication following operation for a tumor of adrenal gland, whether it be cortical or medullary in origin, is adrenal insufficiency. Its treatment is the same as is used when it occurs in Addison's

disease. The more important symptoms of this condition are nausea, vomiting, weakness, a rapid weak pulse, and falling blood pressure. The patient should be checked for the development of these symptoms, as there is a high mortality in those who develop adrenal insufficiency. A valuable aid in the diagnosis of adrenocortical tumors is the quantitative determination of the 17 ketosteroids in urinary assays. Callow, Talbot, and others have worked with this procedure very extensively and have established normal values in children and adults. If the determination of the 17 ketosteroids is 30 milligrams or over, it is very likely to be due to an adrenocortical carcinoma.

Would it not be well to have the lessons that occur so infrequently treated by a group of physicians particularly interested in this field of surgery? Then the intricate details of study and treatment may be carried out more thoroughly and greater progress would be made.

FREDERICK A. BOTHE.

EARLIER ILEOSTOMY IN SEVERE ULCERATIVE COLITIS

THE decision for or against recovery in patients with severe ulcerative colitis is very often settled by the time an ileostomy is done. When patients in the acute stages of ulcerative colitis are permitted to go on to the point where everyone connected with the case—surgeon, physician, and the patient's relatives—agrees that the patient must have an ileostomy in order to save his or her plainly threatened life, the mortality of the procedure will be, and has been, distressingly high.

It is unfortunate that several factors operate to bring about delay in these often severely ill patients. Sometimes these patients have been through previous acute episodes of ulcerative colitis, have spontaneously recovered from

them and have had varying periods of remission from the bloody diarrhea together with the fever and toxicity which is associated with it, thus encouraging them to persist unduly with conservative measures again during subsequent acute episodes. Sometimes the mixed infections superimposed upon these acute ulcerative processes previously have been controlled by sulfasuccinate or some of the other intestinal antiseptics of the sulfa group again encouraging delay and undue dependence upon these agents. Sometimes the physician in charge of a patient in such an acute stage of the disease has not had enough experience with it to be aware how quickly patients with relatively well controlled ulcerative colitis can with but little apparent cause (emotional upsets or associated infections such as influenza) change to states which are real emergencies such as bleeding from the colon which can threaten life by exsanguination progress of the ulcerative process which can and does bring about perforation toxic states as the result of the colon infection which threaten life by the intensity of the infection and nutritional changes and avitaminosis as the result of the frequent loose stools which bring about serious prospects of a fatality.

Added to the above stated deterrents to an early ileostomy is the fact that until recently a patient with an ileostomy was one to be really pitied since there was no adequate way of controlling either the character or the frequency of the liquid discharges from his or her ileostomy no bag which would really keep him from soiling his clothes or smelling and in many of the cases the skin about the ileostomy was so irritated by the discharges from the ileum that in spite of all protective measures patients were constantly disturbed and distressed by an ileostomy.

All of the features of this distressing and serious disease so prejudiced patients their

relatives surgeons gastroenterologists and physicians against this enterostomy that it was delayed in a great many cases with considerable justification until the patient's condition was so desperate that with all of the objectionable drawbacks, ileostomy was accepted rather than the impending and obvious fatality about to occur. Evidence of the truth of these statements is the fact that in our first 80 patients upon whom ileostomy was done our mortality rate was 26 per cent directly the result of the lateness in the acute stage of the disease at which these patients were submitted to ileostomy.

It is because almost all of the drawbacks previously and rightly charged to ileostomy have been overcome that I wish to urge earlier ileostomies followed in many cases by later partial or complete colectomies. We have advocated and practiced early ileostomy for any patient not doing well under medical management committing ourselves to the program of disconnecting the ileostomy and restoring the fecal stream under the following conditions when following the ileostomy the patient has remained free from all symptoms for a considerable time when haustrations as shown by barium enemas have returned to normal in the colon when by sigmoidoscopic examination the lower bowel and rectal mucosa prove normal in appearance and when in addition the patient and family understand that the restoration of the fecal stream may reactivate the ulcerative colitis process and make another and permanent ileostomy necessary.

Many patients with ulcerative colitis may be satisfactorily maintained on a medical regimen (diet, psychogenic control and typhoid vaccine) but when these measures no longer prove satisfactory we urge and practice earlier ileostomy in these patients and have convinced our gastroenterologists and medical consultants of the wisdom and life-saving value of

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE subjects discussed in *Physical Medicine in General Practice*¹ cover the fields of medicine surgery and the specialties in which physical medicine has proved of value either from a therapeutic or diagnostic standpoint. Anyone reading this volume will be convinced that this field of therapy offers many advantages and has wide possibilities. The editor Dr Watkins has assembled a group of contributors all of whom are outstanding in the field. As the result of long practical experience and years of study each of these contributors is in a position to discuss with authority the various subjects that are included under the broad heading of physical medicine.

The contributions have been written primarily for practicing physicians and surgeons. The technical side of physical medicine is minimized and emphasis is placed upon the clinical application of the different techniques in physical medicine to the various conditions most commonly encountered by the practitioner. This book should be in the library of every general practitioner. JOHN S. COULTER.

IN the monograph entitled *The Peripheral Circulations in Health and Disease*² Dr Robert L. Richards has furnished clinicians an excellent review of vascular disorders of the extremities. The monograph is particularly interesting because it presents British and European views and records experiences during the war with peripheral nerve injuries and the immersion foot syndrome. Chapters on occlusive vascular disease and the Raynaud phenomenon are direct and clinically useful and present the stimulating views of Sir Thomas Lewis and George W. Pickering. Practical summary of methods of study of peripheral vascular disease and of anatomical and physiologic phenomena further enhance the value of this monograph. It can be well recommended to those treating patients for disease of the extremities. K. S. GRIFFIN

NO one can read this concise and well written account³ of one hundred cases of advanced cancer by Dr Brunschwig without recognizing the

PATIENTS IN GENERAL PRACTICE. The American Practitioner Series. Edited by Arthur L. Watkins, M.D. Philadelphia, London, and Montreal: J. B. Lippincott Co., 1947.

THE PERIPHERAL CIRCULATION IN HEALTH AND DISEASE. A STUDY IN CLINICAL SCIENCE. By Robert L. Richards, M.D. Foreword by J. R. Leatham, C.B.E., Ch.M. F.R.C.S. Baltimore: The Williams and Wilkins Co., 1946.

RADICAL SURGERY IN ADVANCED ABDOMINAL CANCER. By Alexander Brunschwig, M.D. Chicago: The University of Chicago Press, 1947.

courage and surgical skill that have made possible the results that have been achieved.

The author justly emphasizes the many developments that have made prolonged and difficult surgical procedures possible—massive blood transfusions, continuous spinal anesthesia, parenteral feeding, vitamin therapy, chemotherapy, to mention the most important—but it is obvious that none or all of them can avail unless they are utilized wisely and are combined with discriminating judgment, surgical skill, and a determination not to admit defeat when the possibility of success remains.

After brief introductory chapters dealing with the historical aspect of surgery for abdominal cancer, indications and contraindications for treatment and supportive treatment, the recorded cases are divided into groups according to the anatomical structures chiefly or primarily involved—stomach, small intestine, colon, pancreas, liver, bile passages, spleen, adrenals, and pelvic viscera. A chapter upon injuries to the hepatic artery, portal vein, and superior mesenteric vessels follows the chapter on carcinoma of the extrahepatic bile ducts.

The classification of cases mentioned, however, hardly gives an indication of the extent of the operative procedures carried out. In almost every instance operation involved the removal of diseased structures adjacent to the viscera primarily involved, for example, in a case of primary carcinoma of the pancreas, removal of the tail of pancreas, the spleen, five-sixths of the stomach, umbilicus, and falciform ligament (Case 36, page 195); in a case of primary carcinoma of the splenic flexure, removal of the left half of the transverse colon with its omentum, the spleen, lower three-fifths of the stomach, and the body of the pancreas (Case 38, page 164), following an operation for gastric carcinoma, removal of most of the transverse and descending colon with the omentum, 35 centimeters of jejunum, and 15 centimeters of the ileum (Case 6, page 101). These and other cases with even more extensive involvement are discussed in detail and illustrated with diagrams of the operative procedures and such excellent photographs of surgical specimens that the reader can visualize clearly the serious problems encountered and the surgical procedures applied.

The results obtained by the extensive operative procedures carried out are carefully recorded in each case report and summarized in a final chapter entitled "Results of Radical Surgical Excision in 100 Cases." In 19 of the 100 cases prolonged palliation was obtained and all 19 patients resumed their nor-

The certainty with which such hypotheses are stated as facts suggests a somewhat uncritical scientific approach to the complex problems of hormone interrelationships.

An immense bibliography of 544 items contains only a rare reference to work as late as 1940. It is regrettable that the 20 page English summary could not have been written by one more familiar with the language. On the whole this book has little to offer to the student of endocrinology.

SOMERS H. STURGIS

AN excellent summary of present day gynecologic endocrinology is contained in Dr. Claude Bédère's new book *Diagnostic hormonal et traitements hormonaux en gynécologie*. The book represents however the experience and methods of the author rather than presenting a consensus of opinions. This book is not a bibliographic compilation, says the preface, a statement borne out by only 103 references of which almost two-thirds refer to the author's own papers. The handling of topics is quite dogmatic and inflexible and gives the impression that most endocrine conditions can be easily diagnosed and that treatment is invariably satisfactory and certain.

There are numerous points of difference between contemporary American literature and Dr. Bédère's book to wit:

Although considerable doubt has been cast on the use of progesterone in habitual abortion in recent

DIAGNOSTIC HORMONAL ET TRAITEMENTS HORMONAUX GYNÉCOLOGIE. By Claude Bédère. Paris: Masson et Cie, 1946.

years, Dr. Bédère feels that treatment by corpus luteum hormone gives remarkable results in cases of habitual abortion. In discussing testosterone Hamblen "condemns its use for any reason whatsoever in the female" while Dr. Bédère states that testosterone constitutes the present treatment of choice of functional uterine hemorrhages and advises its use in the treatment of hemorrhages due to uterine fibromyomas, premenstrual mammary pain, precocious breast development and in the treatment of a variety of premenstrual and postmenstrual symptoms. He feels that each time that one wishes to have a direct checking action upon the hypophysis with the minimum of extrinsic action one should use the male hormone.

The subject of sterility is covered in four pages. The physiology of the transport of sperm and egg is briefly discussed. Dr. Bédère states that chronic genital infections and especially gonococcal infections are the principal cause of primary or secondary sterility in women and female sterility is far more frequent than male sterility. He attributes a certain number of cases of female sterility to spasm of the uterine isthmus. There is no discussion of testicular biopsy or of the value of thyroid extract in the treatment of infertility.

In spite of the criticisms that have been made the book is well planned, well arranged, and very clear and definite in its phraseology. It will prove of great value to the general practitioner in France and contains much to interest and challenge the American gynecologist who is interested in endocrinology.

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

ous hospital departments and their personnel nurses, dietitians, medical records librarians, and many other persons directly concerned about hospital progress, will be interested in the discussions of current hospital problems.

The Monday afternoon session will be devoted to a panel discussion on current problems in medical service in hospitals. Tuesday morning to improvement in food service in hospitals. Tuesday afternoon to improvement in nursing service in hospitals. Tuesday evening to a joint session for hospital trustees, medical staff officers, and administrators, Wednesday morning to discussion of personnel and public relations. Wednesday afternoon to a joint session with the American Association of Medical Record Librarians on improving medical records. Wednesday evening to a forum on trends in hospital administration and special hospital problems. Thursday morning to a forum on special problems. Thursday afternoon to a round table conference on problems of the small hospital in meeting the standards of the American College of Surgeons and to a symposium on Graduate Training in Surgery and Thursday evening to a special conference on the point rating system. Detailed programs appear on succeeding pages.

ANNUAL MEETING

The annual meeting of the Governors and Fellows will be held on Thursday afternoon at 1:45. There will be election of officers and governors. The annual meeting affords the Fellows of the College an opportunity to hear reports of officials on the work of the organization and to broaden their knowledge of the methods, and their effectiveness, which are used to raise the professional and ethical standards of surgery and to promote good hospital care and general improvement in the practice of medicine. Each Fellow has a personal part in this work and may extend the influence of the College materially in his local community and wherever his contacts extend. Hospital Standardization particularly offers him wide opportunity to provide better medical care for his patients in the hospital in which he works, through continuous progress in applying the principles of the Minimum Standard which insure the best care of the patient.

Every Fellow will be interested in the reports which will be presented on the following subjects: finances, Hospital Standardization, Graduate Training in Surgery, Medical Motion Pictures, Publications, Public Relations, Library and Literary Research, the work of the state and provincial credentials committees, committees on applicants, and the Committee on History Reviews.

Sectional Meetings, 1947 and the Department of Clinical Research, including cancer clinics and cancer detection centers, the Committee on Cancer Medical Service in Industry and the Committee on Fractures and other Traumas. Dr. Abell, Chairman of the Board of Regents, will report on administration of the College and Dr. Arthur W. Allen will discuss the obligations and opportunities of the Fellows.

MEDICAL MOTION PICTURES

The latest available films demonstrating surgical procedures and related subjects will be shown in the medical motion picture exhibits which will be held daily in The Waldorf Astoria. Motion pictures are a much appreciated feature of the Clinical Congress. Many new pictures on varied subjects are being received by the American College of Surgeons for review. Both sound and silent colored films will be shown during the Congress all of which will have been approved by the Committee on Medical Motion Pictures.

There will also be shown the first of a series of films which are being produced by the College under a grant from the Johnson & Johnson Research Foundation. The film is entitled "Anomalous of the Bile Ducts and Blood Vessels. Structures of the Common Duct," a teaching film of which Dr. Warren H. Cole of Chicago is the author. It is contemplated that there will also be completed in advance of the Clinical Congress at least one additional film which is being produced by the College under the expanded program.

ADVANCE REGISTRATION

The hospitals and medical schools of New York afford accommodations for a large number of visiting surgeons. However in order to insure against overcrowding attendance at the Congress will be limited to the number that can be accommodated at the clinics and meetings. It is therefore expected that surgeons who wish to attend the Congress will register in advance.

Because of greatly increased costs and expenses to which the College will be subjected this year in connection with its New York Clinical Congress the Board of Regents has found it necessary to require a registration fee of \$5.00 for Fellows and for endorsed Junior Candidates. Non-Fellows attending as invited guests of the College will pay a fee of \$10.00. No fee will be required of initiates of the class of 1947.

To each surgeon who registers in advance a formal receipt will be issued. This is to be exchanged for a general admission card upon his registration at headquarters during the Congress.

CLINICAL CONGRESS PROGRAM IN BRIEF

Monday

- 10:00-12:15 General Assembly for Surgeons and Hospital Representatives.
- 1:30- 3:30 Panel Discussion.
- 1:00- 5:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals.
- 1:00- 5:00 Hospital Conference.
- 1:00- 5:00 Surgical Film Exhibition (General)
- 1:00- 5:00 Panel Discussion
- 3:30- 5:00 Presidential Meeting.

Tuesday

- 8:00-12:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals.
- 9:00-12:30 Forum on Fundamental Surgical Problems
- 9:00-10:30 Panel Discussion—Ophthalmology
- 9:30-11:30 Hospital Conference.
- 9:30-11:30 Surgical Film Exhibition (General)
- 10:45-12:15 Panel Discussion—Otorhinolaryngology
- 1:30- 3:00 Panel Discussion.
- 1:00- 5:00 Clinics, Demonstrations—selected local hospitals.
- 1:00- 5:00 Hospital Conference
- 1:00- 5:00 Panel Discussion on Cancer Clinics and Detection Centers.
- 1:00- 5:00 Symposium on Fractures and Other Traumas
- 1:00- 5:00 Surgical Film Exhibition (General)
- 1:00- 4:00 Surgical Film Exhibition (Eye Ear Nose and Throat)
- 3:30- 5:00 Surgical Film Exhibition (Eye Ear Nose and Throat)
- 7:00- 8:00 Hospital Conference.
- 8:00-10:30 Scientific Session General Surgery
- 8:00-10:30 Scientific Session, Ophthalmology
- 8:00-10:30 Scientific Session Otorhinolaryngology

Wednesday

- 8:00- 9:00 Meeting of Cancer Committee.
- 8:00-12:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals.
- 9:00-12:30 Forum on Fundamental Surgical Problems
- 9:00-10:30 Panel Discussion—Ophthalmology
- 9:00-10:30 Hospital Conference.
- 9:30-12:15 Surgical Film Exhibition (General)
- 9:30-12:30 Executive Committees
- 9:30-10:15 Credentials Committees and Committees on Applicants
- 10:15-11:00 Panel Discussion—Otorhinolaryngology
- 10:45-12:15 Meeting of Board of Governors.
- 12:00- 2:00 Meeting of Board of Governors.
- 1:30- 3:00 Panel Discussion.
- 1:00- 5:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals.
- 1:00- 5:00 Symposium on Cancer
- 1:00- 5:00 Surgical Film Exhibition (General)
- 1:00- 4:00 Surgical Film Exhibition (Eye, Ear Nose and Throat)

- 1:00- 5:00 Hospital Conference.
- 3:30- 5:00 Panel Discussion.
- 7:00- 8:00 Surgical Film Exhibition (Eye Ear Nose and Throat)

- 8:00-10:30 Hospital Conference.
- 8:00-10:30 Scientific Session General Surgery
- 8:00-10:30 Scientific Session (Eye Ear Nose and Throat)

Thursday

- 8:00-12:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals.
- 9:00-12:30 Forum on Fundamental Surgical Problems
- 9:00-10:30 Panel Discussion—Ophthalmology
- 9:30-11:30 Surgical Film Exhibition (General)
- 9:30-11:30 Surgical Film Exhibition—Otorhinolaryngology
- 10:45-12:15 Panel Discussion—Governors.
- 1:30- 1:45 Adjourned Meeting, Fellows.
- 1:45- 3:00 Annual Meeting, Fellows.
- 1:00- 5:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals.
- 1:00- 5:00 Hospital Conference.
- 1:00- 5:00 Panel Discussion—Graduate Training in Surgery
- 3:30- 5:00 Panel Discussion
- 3:30- 5:00 Surgical Film Exhibition (General)
- 3:30- 5:00 Surgical Film Exhibition (Eye Ear Nose and Throat)
- 3:30- 5:00 National and Regional Fracture Committees.
- 4:00- 5:00 Committee on the Library
- 7:00- 8:00 Surgical Film Exhibition (Eye Ear Nose and Throat)
- 8:00-10:30 Scientific Session General Surgery
- 8:00-10:30 Scientific Session Ophthalmology
- 8:00-10:30 Scientific Session Otorhinolaryngology

Friday

- 8:00-12:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals.
- 9:00-12:30 Forum on Fundamental Surgical Problems.
- 9:30-10:30 Surgical Film Exhibition (Eye, Ear, Nose and Throat)
- 9:30-12:00 Special Hospital Conference—Point Rating System.
- 10:30-12:00 Surgical Film Exhibition (General)
- 1:30- 5:00 Panel Discussions on each of the following fields, concurrently:
 - Gynecology
 - Obstetrics
 - Plastic Surgery
 - Neurological Surgery
 - Thoracic Surgery
 - Urology
 - Orthopedic Surgery
 - Assembly of Institutes.
- 1:45- 2:15 Assembly of Institutes.
- 2:00- 5:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals.
- 1:00- 5:00 Surgical Film Exhibition (General)
- 3:15-10:00 Convocation

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

ASSEMBLY OF INITIATES

Friday 1 45-3 00 p m

IRVIN ABELL, M.D., Louisville Chairman of the Board of Regents, Presiding
The Program of the American College of Surgeons Hospital Standardization Sectional Meetings, Medical Motion Pictures, Library and Literary Research, Graduate Training in Surgery MALCOLM T. MAC
EACHERN, M.D., Chicago Associate Director and Chairman of the Administrative Board
Fellowship in the American College of Surgeons IRVIN ABELL, M.D., Louisville
The Department of Clinical Research of the American College of Surgeons. CHARLES R. BRANCH, M.D.
Chicago, Assistant Director
Qualifications for Fellowship H. P. SAUNDERS, M.D. Chicago, Assistant Director

EVENING SCIENTIFIC SESSIONS

GENERAL SURGERY

Symposia

Tuesday 8 00-10 30 p m

The Proper Use of Blood and Blood Plasma
A Permanent Red Cross Transfusion Service G. FOARD MCGINNIS, M.D. Washington.
Blood Bank Organization. PAUL I. HOXWORTH, M.D. Cincinnati.
Reactions to Blood Transfusion and the Rh Factor LOUIS K. DIAMOND, M.D. Boston.
The Use of Blood and Plasma in Surgery DALLAS B. PERMISTER, M.D. Chicago

Wednesday 8 00-10 30 p m

Fracture Oration. FRANK D. DICKSON, M.D. St. Louis.
Nutritional Requirements in Surgery
Proper Employment of Oral Feeding. EVERETT I. EVANS, M.D. Richmond.
Parenteral Feeding. ROBERT ELMAN, M.D., St. Louis
The Importance of Adequate Supply of Blood and Nourishment for Wound Healing S. CHAMBERLYN, M.D. New Orleans.

Thursday 8 00-10 30 p m

Hypertension
Fundamental Physiological Considerations. PETER HEINBECKER, M.D. St. Louis.
Indications for Surgery in the Treatment of Hypertension. THOMAS FINDLEY, M.D. New Orleans.
Surgical Procedures in the Treatment of Hypertension. REGINALD H. SMITHWICK, M.D. Boston
End Results in the Treatment of Hypertension. CYRUS C. STURGIS, M.D., Ann Arbor

OPHTHALMOLOGY

Tuesday 8 00-10 30 p m

Epithelial Downgrowth Following Cataract Operation. (Speaker to be announced.)
Local Anesthesia in Ophthalmology. WALTER S. ATKINSON, M.D. Watertown, New York.
Operative Treatment of Vertical Tropia. BRITTAIN F. PAYNE, M.D. New York.
Prevention and Management of Operative Complications During Cataract Extraction. JACK S. GUYTON, M.D. Baltimore.

Thursday 8 00-10 30 p m

Prevention of Infection in Eye Surgery. M. HAYWARD POST, M.D., St. Louis
Glaucoma Following Cataract Extraction. WILLIAM C. OWENS, M.D. Baltimore
Retinal Detachment. HARVEY E. THORPE, M.D. Pittsburgh
The Difficult Cataract Extraction. R. TOWNLEY PATON, M.D. New York.

OTORHINOLARYNGOLOGY

Tuesday 8 00-10 30 p m

Bronchiectasis
Relationship of Bronchiectasis to Sinusitis. ROBERT L. GOODALE, M.D. Boston.
The Surgical Aspects of Bronchiectasis. ALTON OCHSNER, M.D. New Orleans.
The Use of Bronchoscopy in Bronchiectasis. FLETCHER D. WOODWARD, M.D. Charlottesville.

Thursday 8:00-10:30 p.m.

Management of Carcinomas of the Larynx

Treatment by Laryngofissure CHEVALIER L. JACKSON M.D. Philadelphia.

Laryngectomy LOUIS H. CLERY M.D., Philadelphia.

Management of Carcinoma of the Larynx with Metastatic Involvement of the Neck. HENRY B. ORTIZ M.D. Newark.

COMBINED SESSION ON OPHTHALMOLOGY-OTORHINOLARYNGOLOGY

Wednesday 8:00-10:30 p.m.

Blood Supply of Eye and Sinuses. OSCAR A. BATSON M.D. Philadelphia.

Dacryocystorhinostomy HAROLD GIFFORD Jr. M.D. Omaha.

Sinus Surgery in Eye Diseases. (Speaker to be announced.)

Ophthalmoneurologic Symptoms of Nasopharyngeal Tumors. FRANK B. WALSH M.D. Baltimore

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

Tuesday through Friday 9:00 a.m. to 12:30 p.m. - The Waldorf Astoria

Presentation of the results of clinical and experimental research on problems related to general surgery and the surgical specialties which are being currently conducted in many medical schools, clinics, and hospitals.

PANEL DISCUSSIONS

GENERAL SURGERY

Monday 1:30-3:00 p.m.

Pulmonary Suppuration

Moderator EVARIS A. GRAHAM, M.D. St. Louis.

Collaborators BRIAN BLADES, M.D. Washington RICHARD H. OVERHOLT M.D., Brookline, Massachusetts HAROLD NEUFEL M.D. New York.

Monday 3:30-5:00 p.m.

Pancreatitis

Moderator MIMS GAGE, M.D., New Orleans.

Collaborators JOHN M. WAUGH, M.D. Rochester Minnesota HORACE J. MCCORKLE, M.D. San Francisco.

Tuesday 1:30-3:00 p.m.

Surgery of the Spleen

Moderator ALLEN O. WHIFFLE, M.D. New York.

Collaborators GEORGE M. CURTIS, M.D. Columbus, ARTHUR H. BLAKEMORE M.D. New York ROBERT H. E. ELLIOTT M.D. New York LEWIS M. ROUSELOT M.D. New York.

Tuesday 3:30-5:00 p.m.

Jaundice

Moderator CHARLES B. FURSTOW M.D. Chicago.

Collaborators I. S. RAYDON M.D. Philadelphia JAMES T. PRIESTLY M.D. Rochester Minnesota ROSCOE R. GRAHAM, M.D. Toronto.

Wednesday 1:30-3:00 p.m.

Gastric Surgery

Moderator HOWARD K. GRAY M.D., Rochester Minnesota.

Collaborators GEORGE T. PACK, M.D. New York WARREN H. COLE, M.D. Chicago LELAND S. MCKITTRICK M.D. Boston.

Wednesday 3:30-5:00 p.m.

Use of Antibiotic Agents and Chemotherapy in Surgery

Moderator JOHN S. LOCKWOOD M.D. New York.

Collaborators FRANK L. MELNEY M.D. New York C. PHILLIP MILLER, M.D. Chicago HAROLD A. ZINTEL, M.D. Philadelphia Major EDWIN J. POLANSKI, M.C. Fort Sam Houston, Texas.

Thursday 3:30-5:00 p.m.

Surgery of the Hand

Moderator HENRY C. MARRAS, M.D., Boston.

Collaborators HARVEY S. ALLEN M.D. Chicago LAURIE H. MCKIM M.D. Montreal J. HAROLD COUCH, M.D., Toronto.

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

NEUROLOGICAL SURGERY

Friday 1 30-5 00 p m

Late Results of Compound Craniocerebral Injuries
 Moderator A. EARL WALKER, M D, Chicago
 Collaborators JAMES C WHITE, M D Boston COBB PILCHER, M D Nashville

OBSTETRICS AND GYNECOLOGY

Friday 1 30-5 00 p m.

Moderator J MASON HUNDLEY JR. M D Baltimore
Lesions in the Urinary System Engendered by Gynecological and Obstetrical Conditions
 Collaborators (To be announced)
Modern Trends in the Treatment of Malignancies of the Female Genitalia
 Collaborators (To be announced)

ORTHOPEDIC SURGERY

Friday 1 30-5 00 p m

Moderator PAUL B MAGNUSON M D Washington
Evaluation of Reconstruction Operations for Ununited Fractures of the Hip
 Collaborators RUDOLPH S REICH M D Cleveland PAUL C COLONNA M D Philadelphia.
Indications and Operative Techniques for Lumbosacral Fusion of the Spine
 Collaborators (To be announced)

PLASTIC SURGERY

Friday 1 30-5 00 p m

Moderator WILLIAM G HAMM M D Atlanta.
Repair of Surface Defects of the Extremities
 Collaborators FRANK McDOWELL, M D St. Louis TRUMAN G BLOCKER, M D Galveston
Major Facial Defects
 Collaborators BRADFORD CANNON M D Boston WILLIAM B DAVIS, M D Baltimore Major AN
 DREW M MOORE M D Phoenixville CARL E. LISCHER, M D St. Louis.

THORACIC SURGERY

Friday 1 30-5 00 p m

Surgery of the Esophagus
 Moderator STUART W HARRINGTON M D Rochester Minnesota
 Collaborators HERMAN J MOERSCH M.D., Rochester Minnesota CARL EGGERS M D New York.

UROLOGY

Friday 1 30-5 00 p m

Moderator CHARLES C HIGGINS, M D Cleveland.
Management of Renal Lithiasis
 Collaborators GEORGE F CAHILL, M D New York LINWOOD D KEYSER, M D Roanoke
Treatment of Carcinoma of the Bladder
 Collaborators HUGH J JEWETT, M.D., Baltimore ARCHIE L. DEAN M D New York EDWARD N
 COOK, M D Rochester Minnesota.

OPHTHALMOLOGY

Tuesday 9.00-10.30 a.m

Surgery of Extracocular Muscles
 Moderator HAROLD W BROWN, M D, New York.
 Collaborators RUDOLF AEBEL, M D New York WALTER H FINK, M D Minneapolis

Surgery of Glaucoma

Wednesday 9.00-10.30 a.m.

Moderator C. S. O'BRIEN M.D. Iowa City

Collaborators P. ROBB McDONALD, M.D. Philadelphia JOHN S. MCGAVIC, M.D. Bryn Mawr WILLIS S. KINGTON M.D., New York.

Angiopathic Ocular Lesions

Thursday 9.00-10.30 a.m.

Moderator (To be announced)

Collaborators WALTER F. DUGGAN M.D. Utica FRANK D. CARROLL, M.D. New York HERMAN ELWYN M.D. New York

OTORHINOLARYNGOLOGY

Tuesday 10.45 a.m.-12.15 p.m.

The Use of Antibiotics in Ear, Nose and Throat Surgery

Moderator CHESTER S. KEETTER, M.D. Boston.

Collaborators WESTLEY M. HUNT M.D. New York FREDERICK T. HILL, M.D. Waterville Maine-LEIGHTON F. JOHNSON M.D. Boston.

Wednesday 10.45 a.m.-12.15 p.m.

Rehabilitation of the Larynx in Bilateral Adductor Paralysis of the Vocal Cords

Moderator GABRIEL TUCKER M.D. Philadelphia.

Collaborators DEGRAAF WOODMAN M.D. New York BRIEN T. KING, M.D., Seattle ALBERT C. FURSTENBERG, M.D. Ann Arbor

Thursday 10.45 a.m.-12.15 p.m.

Anesthesia for Ear, Nose and Throat Surgery

Moderator LLOYD H. MOUSEL, M.D. Washington.

Collaborators (To be announced)

SYMPOSIUM ON FRACTURES AND OTHER TRAUMAS

Tuesday 2.00-5.00 p.m.

ROBERT H. KENNEDY, M.D. New York Chairman Committee on Fractures and Other Traumas, Presiding.
Appraisal of Present Methods of Treatment

Intraosseous Fractures of the Neck of the Femur PAUL C. COLOMBA, M.D. Philadelphia Professor of Orthopedic Surgery University of Pennsylvania School of Medicine.

Fractures of the Upper Extremity of the Tibia Involving the Knee Joint. EDWIN F. CAVE, M.D. Boston Instructor in Orthopedic Surgery Harvard Medical School.

Injuries of the Intervertebral Disc. FRANK H. MATTHEW, M.D. Cincinnati Assistant in Clinical Surgery University of Cincinnati College of Medicine.

Fractures of the Os Calcis. JAMES J. CALLAHAN M.D. Chicago Professor Bone and Joint Surgery Loyola University School of Medicine.

Bone Plates and Screws. ROBERT B. KENNEDY M.D. New York Associate Clinical Professor of Surgery Columbia University College of Physicians and Surgeons.

SYMPOSIUM ON GRADUATE TRAINING IN SURGERY
AND THE SURGICAL SPECIALTIES

Thursday 3.30-5.30 p.m.

Moderator DALLAS B. FREEMAN, M.D. Chicago Professor and Chairman, Department of Surgery Chicago, Surgeon University of Chicago Clinics Chairman Graduate Training Committee American College of Surgeons.

Centralized Plan of Graduate Training in Surgery. MAX M. ZIMMERER, M.D. Cincinnati Professor of Surgery University of Cincinnati College of Medicine

Graduate Training from the Standpoint of Decentralized Residency Training in Hospitals Affiliated with a Medical School. ALBERT C. FURSTENBERG, M.D. Ann Arbor Professor of Otolaryngology Dean, University of Michigan Medical School.

The Place of the Organized Clinic in Graduate Training in Surgery RICHARD B. CATTELL, M.D. Boston Surgeon, Lahey Clinic.

Graduate Training in General Surgery and the Surgical Specialties in a Veterans Hospital. CHARLES B. PUESTOW M.D. Chicago Clinical Professor of Surgery University of Illinois College of Medicine

Discussion Opened by FREDERICK A. COLLIER M.D. Ann Arbor Chairman of the Committee on Relations of the American College of Surgeons with American Boards of Surgery, and FRANK D. GURD M.D. Montreal Professor of Surgery McGill University Faculty of Medicine.

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS HOSPITAL STANDARDIZATION CONFERENCE GENERAL ASSEMBLY JOINT SESSION—SURGEONS AND HOSPITAL REPRESENTATIVES

Monday 10 00 a.m.—12 30 p.m. (See program on preceding pages.)

PANEL DISCUSSION—CURRENT PROBLEMS IN MEDICAL SERVICE IN HOSPITALS

Monday 2 00—5 00 p.m.—Seri Room—
First Floor—The Waldorf Astoria

Conducted by JOSEPH TURNER, M.D., New York Director
Mount Sinai Hospital.
Integration of the General Practitioner in the Hospital
Medical Staff Organization. HARRY R. MCKELSON,
M.D., Cincinnati President, The Society of General
Physicians.
The Professional Audit to Control Efficiency. FREDERICK
T. HILL, M.D. Waterville, Maine Medical Director
Thayer Hospital.
What is Major and Minor Surgery? Who Should be Per-
mitted to do Major Surgery in an Approved Hospital?
J. J. GOLDBERG, M.D., New York Director Hospital for
Joint Diseases.

Medical Staff Conferences Essential to Medical Progress
and Good Care of the Patient. JOSEPH C. DOANE, M.D.,
Philadelphia, Medical Director Jewish Hospital and
Professor of Clinical Medicine, Temple University
Medical School, University of Pennsylvania.
Moderator. EVERETT W. JONES, Chicago Vice-Pres-
ident, Modern Hospital Publishing Company

8 00—10 30 p.m.—Ballroom—Fourth Floor—
The Waldorf Astoria
Presidential Meeting

Hospital representatives attending the Twenty-Sixth An-
nual Hospital Standardization Conference are most cor-
dially invited to attend the Presidential Meeting

PANEL DISCUSSION—IMPROVING FOOD SERVICE IN HOSPITALS

Tuesday 9 30 a.m.—12 30 p.m.—East Ballroom—
Hotel Commodore

Conducted by MARGARET GILLAM, Chicago Dietary Con-
sultant, American Hospital Association
New Developments in the Field of Nutrition and How They
Affect Food Service and the Care of the Surgical Pa-
tient. ROBERT ELKMAN, M.D. St. Louis, Professor of
Clinical Surgery Washington University School of
Medicine.
New Equipment and Methods to Relieve Problems of
Food Service Conducive to Complaints and Dissatisfac-
tion on the Part of the Patient. EVERETT W. JONES, Chi-

cago Vice-President, The Modern Hospital Publishing
Company
Food Service an Important Factor in Personnel and Public
Relations. PAUL H. PHELPS, Oklahoma City Adminis-
trator University of Oklahoma Hospitals
The Importance of Good Interdepartmental Relations of
the Dietary Department and How They can be Im-
proved. ANTHONY W. ECKERT, Neptune, New Jersey
Administrator Flitkin Memorial Hospital.
Personnel Problems in the Dietary Department. ALLAN E.
MOSSO, New York, Chief Dietitian St. Luke's Hospital
Question and Answer Period
Problems of Food Service in Hospitals

PANEL DISCUSSION—IMPROVING NURSING SERVICE IN HOSPITALS

Tuesday 2 00—5 00 p.m.—Seri Room—
First Floor—The Waldorf Astoria

Conducted by CLAUDE W. MUMFORD, M.D. New York,
Director St. Luke's Hospital and Professor in Hospital
Administration Columbia University
Report of Survey Made by American College of Surgeons
on use of Nurses' Aides. HOWARD C. NAFFZGER, M.D.
San Francisco Professor of Surgery University of Cali-
fornia Medical School Surgeon-in-Chief University
Hospital.
Student Nurse Recruitment—the 1947 Campaign and the
1948 Prospects. MILDRED REES, R.N. Detroit Super-
intendent, Children's Hospital Detroit Chairman Stu-

dent Nurse Recruitment Committee, American Hospital
Association.
Utilization and Training of Practical Nurses and Auxiliary
Workers. ELIZABETH C. PHILLIPS, R.N., Rochester
New York Chairman, Joint Committee on Auxiliary
Nursing Service.
How Hospitals Can Help in Student and Practical Nurse
Recruitment. EMILY K. JOHNSON, New York, Public
Relations Associate, American Nurses Association.
Correlation of the Services of the Graduate Nurse, the
Practical Nurse, and the Nurses Aide. EDWARD M.
BERNECKER, M.D. New York Commissioner Depart-
ment of Hospitals, City of New York.
Question and Answer Period.

JOINT SESSION FOR HOSPITAL TRUSTEES MEDICAL STAFF OFFICERS, AND ADMINISTRATORS

Tuesday 8:00-10:30 p.m. — *Sert Room*—

First Floor—The Waldorf Astoria

RAYMOND P. SLOAN, New York, Editor, *The Modern Hospital*, Presiding.

Statement by the Chairman, RAYMOND P. SLOAN.

Working Together—Hospital Trustees, Members of the Medical Staff and the Administrator Must Co-operate in Assuring Good Care of the Patient in the Hospital. JONAS H. HAYES, New York, Superintendent, Lenox Hill Hospital, President, American Hospital Association. Regionalization of Hospitals. EDWARD J. NOBLE, New

York, Chairman of the Board, American Broadcasting Company and Chairman, Lili Savers Corporation.

The Hospital Trustee Self Analysis—Do I as Trustee Know that my Hospital Lives up to the Standards set down by the American College of Surgeons and Carries out Effectively the Four Primary Functions of the Hospital. WILLIAM HENRY JACKSON, New York, President, New York Hospital.

A New Era in the Education and Training of Hospital Administrators. CLAUDE W. MURPHY, M.D., New York, Superintendent, St. Luke's Hospital, Professor of Hospital Administration, Columbia University.

PANEL DISCUSSION—PERSONNEL RELATIONS AND PUBLIC RELATIONS

Wednesday 9:30 a.m.—12:30 p.m. — *Sert Room*—

First Floor—The Waldorf Astoria

Conducted by FRANK R. BRADLEY, M.D., St. Louis, Director, Barnes Hospital, President, American College of Hospital Administrators.

Better People Make Better Hospitals—Good Person of Relations Can Improve Quality of Personnel. EDGAR C. HAYROW, East Orange, New Jersey, Director, East Orange General Hospital, President Elect, American College of Hospital Administrators.

Personnel Relations Affect Public Relations. OLIVER G. PRATT, Providence; Executive Director, Rhode Island Hospital.

Why Every Hospital Should Have—(a) A Personnel Director and Define Personnel Policies, (b) Some Person Definitely Assigned Over-all Responsibility for Public Relations. FRANK D. MOOREY, M.D., Buffalo, Super-

tendent, Buffalo General Hospital, Associate in Medicine, University of Buffalo School of Medicine.

Orientation and Training of Hospital Personnel. MARY JOHNSON, Ph.D., New York, Research Associate, Program in Hospital Administration, Columbia University. Why Hospitals Must Consciously Enter Competition for the Public's Attention and What Means They Can Ethically Employ. CONNOR M. SMITH, New York, President, WUL, Folsom and Smith.

Round Table Conference on Media for Informing the Public Regarding Hospitals.

Newspapers
Radio
Hospital Publications (c) Tours and Demonstrations
Films and Slides
Forums and Talks

Conducted by JOHN GORRILL, M.D., New York, Associate Professor of Hospital Administration, Columbia University.

PANEL DISCUSSION—IMPROVING MEDICAL RECORDS IN HOSPITALS—JOINT SESSION WITH THE AMERICAN ASSOCIATION OF MEDICAL RECORD LIBRARIANS

Wednesday 2:00-5:00 p.m. — *Sert Room*

First Floor—The Waldorf Astoria

Conducted by ROWEN C. BUREKI, M.D., Philadelphia, Director of Hospitals, University of Pennsylvania, Dean, Graduate School of Medicine.

A Message from the President of the American Association of Medical Record Librarians. EDNA C. BLACK, R.R.L., New Haven, Medical Record Librarian, Grace Unit, Grace-New Haven Hospital; President of the American Association of Medical Record Librarians.

The Present Status of Training Medical Record Librarians Through—

(a) Approved Schools. EDNA K. HOFFMAN, R.R.L., Chicago, Chief Medical Record Librarian, Wesley Memorial Hospital, Director, Program in Medical Record Science, Northwestern University.

(b) In Service Training Institutes. MARGARET C. TAYLOR, R.R.L., Chicago, Field Instructor, In-Service

Extension Courses, American Hospital Association. The Problems of the Supply and Demand for Medical Record Librarians in Hospitals. ADALDIE C. HAYDEN, R.R.L., Chicago, Executive Secretary, American Association of Medical Record Librarians.

The Proper Approach to the Maintaining of Adequate Medical Records. MARGARET DUBOIS, M.D., Richmond, Assistant Director, Hospital Division, and Associate Professor of Hospital Administration, Medical College of Virginia School of Medicine.

The Responsibility of the Medical Staff of the Hospital in Maintaining Good Medical Records. MALCOLM T. MACFARLANE, M.D., Chicago, Associate Director, American College of Surgeons.

Impressions of the Field Representative of the American College of Surgeons in regard to Maintaining Adequate Medical Records. REAR ADMIRAL LUCIUS W. JOHNSON, San Diego, Assistant, Hospital Department, Assigned to Pacific Region.

Question and Answer Period.

PRELIMINARY PROGRAM—1947 CLINICAL CONGRESS

A FORUM ON TRENDS IN HOSPITAL ADMINISTRATION NEW IDEAS AND PROCEDURES AND SPECIAL HOSPITAL PROBLEMS

Wednesday 8:00-10:30 p.m.—Sert Room—
First Floor—The Waldorf Astoria

Participation in the Forum on Hospital Trends New Ideas New Procedures and Special Hospital Problems will be on a voluntary basis, that is those having something to

contribute will please communicate with
Dr. Malcolm T. MacEachern, Associate Director
American College of Surgeons Chicago
Discussion Leader LEO M. LYONS, Chicago Director St.
Luke's Hospital
Ten minutes will be allowed each participant.

FORUM ON SPECIAL PROBLEMS

Thursday 9:30 a.m.—12:30 p.m.—Sert Room—
First Floor—The Waldorf Astoria

Coordinators ROSE C. BURKE, M.D. Philadelphia Di-
rector of Hospitals, University of Pennsylvania Dean
Graduate School of Medicine and EVERETT W. JONES,
Chicago Vice-President, The Modern Hospital Publish-
ing Company
Topics for Discussion
The Modern Hospital—a Complete Synchronized Entity
New Developments in Each Group of Departments
that Provide Unified Service to the Patient.
What Has Been Done to Meet the Present Acute Bed
Shortage?
Present Status of Volunteer Workers in Hospitals.
Hospital Trustees Members of the Medical Staff Nurs-
ing Executives and Administrators Must Cooperate in
Better Nursing Relations.

Are We Making Progress in the Care of the Chronically
Ill?
Hospitals and the Cancer Problem—Cancer Clinics and
Cancer Detection Centers.
Newer Services for the Modern Hospital—Physical
Medicine and Geriatrics.
Planned Convalescence and Its Place in the Community
Adjusting Hospital Service to Medical Progress.
Interdepartmental Relations of the Pharmacy How to
Enhance Its Value and Appreciation by other Depart-
ments in the Hospital.
The Expanding Educational Responsibilities of the Ho-
pital.
Proper Use of the Medical Library
Incentives to Hold Employees—Including Retirement
Plans.
Collaborators
(To be listed later)

ROUND TABLE CONFERENCE—SPECIAL PROBLEMS OF THE SMALL HOSPITAL IN MEETING THE STANDARDS OF THE AMERICAN COLLEGE OF SURGEONS

Thursday 2:00-5:00 p.m.—Sert Room—
First Floor—The Waldorf Astoria

Conducted by HARVEY AGNEW, M.D. Toronto Secretary
Canadian Hospital Council Editor of *Canadian Hos-*
pitals

Topics for Discussion
Medical Staff Organi-
zation
Clinical Laboratory
X-ray Service
Medical Records
Nursing Service

Food Service
Pharmacy Service
Personnel Management
Public Relations
Care of Emergencies

Collaborators
ALLAN CRAIG, M.D., New York Hospital Consultant.
JANE S. DAVIS, M.H.A., Niles, Michigan Superintendent,
Pawating Hospital.

EVA H. ERIKSSON, M.H.A., Olean New York Super-
intendent, Olean General Hospital.
EDMUND B. FERNIVAL, M.H.A., Syracuse, Administra-
tor, Syracuse Memorial Hospital.
WILLIAM C. ILLINOIS, White Plains, New York Ad-
ministrator White Plains Hospital.
GEORGE PRICE, Philadelphia Administrator Jewish
Hospital.
MARSHALL L. PICKENS, Charlotte Assistant Secretary
The Duke Endowment.
WILLIAM P. SLOVER, Manchester Connecticut Super-
intendent, Manchester Memorial Hospital.
ISABELLA N. WILLIAMS, Norwich, New York Adminis-
trator Chenango Memorial Hospital.
ROBERT G. WRIGHT, Alexandria Administrator A
lexandria Hospital President, The Hospital Council of
the National Capital Area.

SPECIAL CONFERENCE ON THE POINT RATING SYSTEM

Thursday 8:00-10:00 p.m.—Sert Room—
First Floor—The Waldorf Astoria

A Special Conference on the Point Rating System for Hos-
pitals with Particular Discussion of Evaluation and

Rating of Hospitals Under this system.
Conducted by HARVEY AGNEW, M.D. Toronto Secret-
Canadian Hospital Council, and HENRY G. FARMER, M.
A., M.D. Chicago Assistant, Hospital Department
American College of Surgeons.

PRELIMINARY CLINICAL PROGRAM

CLINICS IN NEW YORK HOSPITALS

Monday

BELLEVUE HOSPITAL—THIRD (NEW YORK UNIVERSITY) SURGICAL DIVISION

Radiology—Demonstrations. (I & K Building, Ground Floor) ISA I. KAYLAN and STAFF. The Radiologic Treatment of Benign and Malignant Superficial Lesions—Irradiation Alone and as an Adjunct to Surgery.

9:00-4:00. **Röntgenology**—Roentgen Demonstrations of Surgical Diseases. LEWIS J. FREEDMAN and STAFF (I & K Building, Ground Floor).

Surgical Lesions of the Small Bowel Roentgenologically Considered. J. BUCKSTEIN.

Surgical Problems of the Chest. P. STRAUSS.

Diagnostic Problems in Osseous Disease. M. ZUKERMAN.

Diagnosis of Renal Surgical Disease. H. ZUKERMAN.

Interesting Neurosurgical Cases. LEWIS J. FREEDMAN, HERBERT LORBER.

BELLEVUE HOSPITAL—FOURTH (NEW YORK UNIVERSITY) SURGICAL DIVISION

30-3:30. **Surgery Specialties**. (Operating Rooms K-5 & K-6).

Children's Surgery—Hernia. PHILIP ALLEN (Operating Room A).

Children's Surgery—Chest. CHARLES W. LESTER (Operating Room B).

Maxillofacial Surgery—Surgical Correction of Prognathism of the Mandible. LEO WINTER (Operating Room C).

Orthopedic Surgical Clinic. ARTHUR KRIDA, JOHN McCARTHY (Bone Room K-6).

BETH ISRAEL HOSPITAL

5:00-5:30. **Otorhinolaryngology**. Clinical Demonstration of Endoscopic Treatment and Results. MAX SOM and STAFF.

5:30-6:00. **Ophthalmology**. GREINER and STAFF.

FLOWER AND FIFTH AVENUE HOSPITALS

100-4:00. **Neurosurgery**. "Slipped Disc" Operation and End-Results. THOMAS I. HOOKER.

4:00-5:00. **Thoracic Surgery**. Trauma to Neck Involving the Mediastinum—or—Mediastinal Tumors. MILTON J. LLOYD.

HARLEM HOSPITAL

5:00-5:30. Symposium on Burns and Plastic Surgery. F. X. THOMAS, J. A. TAMERIN, A. GARDNER and STAFF.

HOSPITAL FOR JOINT DISEASES

9:00-100. **General Surgery**. Operative Clinic: Tendon Transplantation on the Hand. Transpositional Osteotomy at the Hip. LEO MAYER, HENRY MILCH. Follow-up Demonstration.

Result of Hallux Valgus Operation. PAUL LARSEN.

2. (a) Transplantation of Extensor Carpi Ulnaris Tendon to Give Abduction of the Thumb; (b) Meniscectomy of the Temporomandibular Joint; (c) Fracture of Xiphoid-Xiphoidectomy; (d) Osteotomy Fusion of Hip. MICHAEL BURMAN.

See the "Daily Clinical Bulletin" for Final Program.

3. () Slipping of the Femoral Epiphysis and Results by the Use of Internal Rotation Brace; (b) Result of Osteotomy of the Hip Combined with Resection of Femoral Head. HENRY MILCH.

4. (a) Case Illustrating the Results of Tendon Transplantation and Nerve Suture; (b) Cases Illustrating Surgery of the Hand.

5:00-4:00. **General Surgery**. Operative Clinic: Surgery of the Hand. LEO MAYER.

6:00-4:00. **Otorhinolaryngology**. Operative Clinic: Nose and Throat Surgery. L. KLEINFELD.

LYING-IN HOSPITAL

(See New York Hospital)

MANHATTAN EYE, EAR AND THROAT HOSPITAL

5:00-6:00. **Ophthalmology**. Demonstration: Scleral Demonstration. G. BOWACOLLO.

Demonstration. Corneal Grafting Technique on Rabbits. H. M. KATZ.

7:00-8:00. **Otolaryngology**. Demonstration: Bipolar Floor Otectomy and Laminography. W. R. CANNON.

3:00-4:00. **Ophthalmology**. Demonstration. Cases of Cataract Surgery Complicated by Glaucoma. M. A. LESTER.

METROPOLITAN HOSPITAL

5:00-4:00. **Neurosurgery**. Peripheral Vascular Clinic Including Sympathectomy. LOUIS R. KAUFMAN, S. THOMAS OLIVER, ALBERT LEWIS, KENNETH C. FRANK, DAVID SCHERER.

MONTFIORE HOSPITAL

6:00-4:00. **General Surgery**. Nonoperative Clinic: SAXUEL STANDARD and STAFF.

4:00-5:00. **General Surgery**. Nonoperative Clinic: Neoplastic Diseases. DANIEL LASELO.

MOUNT SINAI HOSPITAL

8:30-100. **Gynecology**. Operative and Nonoperative Clinic: (Surgical Amphitheatre).

Parametrial Fixation Operation (F.bergill). Surgical Treatment of Urinary Stricture Incontinence with Testicular Plate. M. A. GOLDBERGER.

Conservative Surgery for Pelvic Endometriosis. JOSEPH GARDNER.

The Value of the Twenty-four Hour Pregnancy Test: A Review of 500 cases. EMANUEL KLEINBERGER.

The Clinical Value of Hystero-graphy. ARTHUR DAVIES.

The Management of the Menopause. ROBERT I. WATSON.

NEW YORK EYE AND EAR INFIRMARY

2:30-3:30. **Otorhinolaryngology**. Nonoperative Clinic: Frontal and Ethmoid Sinusitis—Preoperative and Follow-up.

3:30-5:30. **Otorhinolaryngology**. Nonoperative Clinic: Adenoid Sinusitis—Preoperative and Follow-up. EARL F. LINDEN.

4:00-6:00. **Otorhinolaryngology**. Operative Clinic: Sinus Surgery. STUART L. CRANE.

4:00-6:00. *Otolaryngology* Operative Clinic Surgery of the Antrum.

Ophthalmology Nonoperative Clinic Preoperative Diagnostic Study **BERENS, ROMAN and ASSOCIATES.**

Preoperative and Postoperative Glaucoma Studies. **KNIGHTON ELWYN and ASSOCIATES.**

Plastic Surgery Methods. **HUGHES, COLE and ASSOCIATES**

Special Lenses—Contact, Anisclonic and Telescopic.

The routine clinics of the New York Eye and Ear Infirmary will be held as usual during this period. All Fellows of the American College of Surgeons are cordially invited to attend.

NEW YORK HOSPITAL

9:00-12:00. *Genitourinary Surgery* Demonstration Surgical Anatomy **ERIKST LAMPE.**

1:00- General Surgery Demonstration Surgical Anatomy Detailed Anatomy of Radical Neck Dissection **ERIKST LAMPE.**

2:00- *Otolaryngology* Operative Clinic Reconstruction of the Nose. **ARTHUR PALMER.**

NEW YORK HOSPITAL
LYING-IN HOSPITAL
Lying In Hospital Staff Conference.

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL

8:00- *Orthopedic Surgery* Operative Clinic. **ALAN DE FOREST SMITH and STAFF** (Capacity 16)

1:30- *Orthopedic Surgery* General Orthopedic Clinic **HALFORD HALLOCK and STAFF**
Congenital Club Foot Clinic **JOHN McCauley**

NEW YORK POST GRADUATE MEDICAL SCHOOL AND HOSPITAL

9:00-11:00. *General Surgery* Operative Clinic (Amphitheatre, 6th Floor) Diseases of Gall Bladder and Bile Ducts

11:00-12:00. *General Surgery* Nonoperative Clinic (Erdmann Auditorium) Follow-up Results.

2:00-3:00. *General Surgery* Operative Clinic (Amphitheatre, 6th Floor)

CLINICS IN BROOKLYN—LONG ISLAND HOSPITALS

Monday

PRESBYTERIAN HOSPITAL

1:00-4:00. *General Surgery* Nonoperative Clinic Carcinoma of the Tongue at a General Hospital, Analysis of 100 cases. **JOHN M. HANFORD**

Lymphatic Spread of Carcinoma of the Rectum and Colon **ROBERT S. GRIMOKEL.**

Roentgen Diagnosis of Carcinoma of the Stomach Ross Golden

Extent of Resection of Stomach for Carcinoma, Correlation with Experimental Mucus Transformation. Case Demonstration. **EDWARD L. HOWES**

Chemotherapy of Malignancy with Nitrogen Mustard. **ALFRED GILLINOR**

Surgical Anatomy Demonstration of Autonomic Nerve Supply of the Gastrointestinal Tract. **JOSE FERRER.**

Structure of the Female Perineum. **PHILIP WISEDELL.**

PRESBYTERIAN NEW YORK ORTHOPEDIC HOSPITALS

Fracture Service

1:30-4:00. *Fractures and Traumatic Surgery* Fracture Clinic The Low Back Problem. **SAWYER R. GASTON**
Three, Four and Five Year Hip Fracture Follow-up Results **CHARLES S. NEER.**

ROOSEVELT HOSPITAL

2:00- *Discussion* Post-Graduate Education of the Surgical Residents and Interns. **CHARLES F. STEWART**

3:30- *Fractures and Traumatic Surgery* Traumatic and Reconstructive Surgery of the Hand.

The Early Treatment of Hand Injuries (Emergency Treatment) **CONRAD W. CUTLER.**

The Repair of Finger Tip Injuries. **HENRY A. KROSBURY**

The Temporary Repair of Severed Flexor Tendons of the Fingers. **R. STERLING MULLER**

Reconstructive Surgery of the Hand. **WILLIAM LITTLE**

St. LUKE'S HOSPITAL

8:30-11:00. *General Surgery* Operative Clinic. **WILLIAM MACFEE and STAFF**

11:00-12:00. *General Surgery* Clinical Demonstrations Neurofibromas of Stomach, six cases **JOHN WEST**

Management of Polyps of Colon and Rectum. **PAUL MORTON**

Adenocarcinoma of Colon and Rectum with Metastasis to Ovaries Illustrative cases **WILLIAM BEERY**

Malignant Tumors of the Appendix **STAFFORD WEAVER**

2:00-3:00. *Orthopedic Surgery* Operative Clinic. **MATTHEW CLEVELAND and STAFF**

ST VINCENT'S HOSPITAL

9:00- *General Surgery* Operative Clinic. **RAYMOND P. SULLIVAN JOHN A. LAWLER and GEORGE R. STUART EDWARD DENKEM**

9:00- *Thoracic Surgery* Group Conference Selection of Cases for Thoracoplasty Lobectomy and Pneumectomy **DANIEL MULVHILL**

9:00- *Radiology* Nonoperative Clinic Roentgen Diagnosis of Thoracic Tumors. **WILLIAM W. MAYER and ASSOCIATES.**

10:00- *Neurosurgery* Nonoperative Clinic Follow-up Study of a Series of Hemilaminectomies with Fusion of Spine. **JAMES T. DANIELS, ANTHONY PIRANI.**

2:00- *Pathology* Clinical Pathological Demonstration of Hodgkin's Disease. **ANTHONY ROTTINO JOHN KEATING, WILLIAM F. MEEHAN**

Growth of Tissue Anterior Chamber of the Eye of Mice Display and Demonstration of Systemic Diseases b

Kodachrome Slides.

Display of Fixed Specimens

VETERANS ADMINISTRATION HOSPITAL

1:00- General Surgical Conference. **FREDERIC W. BANCROFT FORDYCE B. ST JOHN ALLEN O. WHIFFLE**

FLOWER AND FIFTH AVENUE HOSPITALS

- 9:00-12:00. A New Operation for Pilonidal Cyst. JOHN HERBLEN. Preoperative and Postoperative Care. LOUIS R. KAUFMAN and WHITEFIELD STAFF.
- 1:00-12:00. Test of Viability of Bowel. JOHN HERBLEN, KURT LANGE, & THOMAS GLASSER.
- Intestinal Obstruction. ROBERT T. CROWLEY
- 2:00-4:00. *Orthopedic Surgery*. ANTHON H. BINGHAM.
- Plastic Surgery. DAVID M. MAYER, CLARENCE R. STRAATMAN, JOHN F. FORD.
- Urology. SPRAGUE CARLTON and STAFF
- Touching Exhibit in Outpatient Department.
- McGregor Orchidectomy. L. P. WEBSTER.
- Fractures. Fracture Treatment—Many Pictures and End-Results—Demonstrations. MILTON J. WILSON and STAFF

GOLDWATER MEMORIAL HOSPITAL—THIRD SURGICAL DIVISION

- 9:00-1:30. *Geriatric Surgery*. Operative Clinic. Refrigeration in Clinical Surgery. ROOSTER.
- Primary Closure in Amputations of Lower Extremity. TORRES.
- Herniorrhaphy in the Aged. STANLEY BROWN.
- Arteriotomy. SCHMATERSON.
- Peritonitis in the Aged. CARR.
- 11:30-12:00. Ward Rounds.
- 12:00-4:30. *Geriatric Surgery*.
- The Treatment of Varicose Ulcers by Ligation of Femoral Vein. KIMMEL.
- Prostatectomy in the Aged. DOUBILET.
- Prostatectomy in the Complicated Case. BERNSTEIN.
- Interesting Urological Conditions in the Aged. STANLEY.
- Intravenous Procaine in Surgery. OPPENHEIM.
- Arteriology. TORRES.
- Combined Lumbar Sympathectomy and Vein Ligation for Peripheral Vascular Disease. SHARROFF.
- 4:30-6:00. Forum on Surgical Investigation by Postgraduate Class of Surgery.

HARLEM EYE AND EAR HOSPITAL

- 8:00-9:00. *Otolaryngology*. Operative Clinic: Tonsillectomies with Medial tonsil enucleator.
- 9:00-10:00. *Ophthalmology and Otorhinolaryngology*. Operative Clinic: Major Eye, Ear, Nose and Throat Surgery.
- 10:00-11:00. *Otorhinolaryngology*. Demonstration: Demonstration of Ear, Nose and Throat Cases.
- 10:00-11:00. *Otorhinolaryngology*. Operative Clinic: Rhinoplasty Surgical Case.
- 12:00-1:00. *Otorhinolaryngology*. Operative Clinic: Lid Plastic.

HARLEM HOSPITAL

- 9:00-12:00. *General Surgery*. Symposium in Lymphogranulosis and Rectal Strictures. Ward Rounds. L. T. WRIGHT, J. G. LEVY and STAFF.
- 10:00-12:00. *Gynecology*. Symposium. H. C. FALK, P. M. MURRAY, and STAFF.
- Operative Clinic in Gynecological Surgery.
- Nonoperative Clinics: (a) Management of Postabortal Infection. (b) Management of Recurrent Salpingitis. (c) Management of Pyosalpinx Complicating Fibroid with End-Results.

HOSPITAL FOR JOINT DISEASES

- 9:00-12:00. *Orthopedic Surgery*. Operative Clinic: Nerve Resection. Painful Arthritis of Hip Joint. ISADORE ZADEK.

Surgical Anatomy. Mechanism of Motion of Thumb

- EMANUEL KAPLAN.
- 2:00-4:00. *Genitourinary Surgery*. Operative Clinic: Hemorrhoids, Fistulas and Benign Adenoma of Rectum. Pilonidal Cyst. Nonoperative Clinic: Lymphogranuloma Venereum. HARRY GOLDMAN.
- 2:00-4:00. *Genitourinary Surgery*. Operative Clinic: Surgery of the Kidneys, Ureter and Bladder. PAUL ACKER.
- 4:00-5:00. *Plastic Surgery*. Operative Clinic: Nasoplasty. Follow-up Clinic: Nasal Lip and Face Plastics. LEO GOLD GLUMER.

HOSPITAL FOR SPECIAL SURGERY

- 8:30-10:00. *Orthopedic Surgery*. Operative Clinic. Children's Service.
- 9:00-10:00. *General Surgical Problems*. BEEHMAN, GRACE, COLEY and STAFF.
- 2:00-5:00. *General Surgical Problems and Plastic Surgery*.

LYING-IN HOSPITAL

(See New York Hospital)

MANHATTAN EYE, EAR AND THROAT HOSPITAL

- 9:00-10:00. *Ophthalmology*. Demonstration of Anisocoria. Clinic. A. LEVINE.
- 9:00-10:00. *Ophthalmology*. Operative Clinic: Plastic Operations of Eye. BYRON SMITH.
- 9:00-10:00. *Otolaryngology*. Demonstration: Postoperative Cases. M. P. JONES, R. J. BELLROCK.
- 9:30-10:00. *Ophthalmology*. Demonstration, Glaucoma Clinic: Late Results of Glaucoma Surgery. F. L. F. KORN.
- 10:00-11:00. *Ophthalmology*. Demonstration: Corneal Grafting Technique on Rabbit. H. M. KATZ.
- 10:00-11:00. *Otorhinolaryngology*. Operative Clinic and Demonstration: Operation for Polypoid Sinusitis and Demonstration of Postoperative Cases. A. NAGEL.
- 11:30-12:00. *Otolaryngology*. Bronchoscopic Clinic: Diagnosis and Treatment. D. S. CHODURA.
- 12:00-1:00. *Otolaryngology*. Operative Clinic: Fenestration Operation. M. P. JONES.
- 12:00-1:00. *Ophthalmology and Otorhinolaryngology*. Demonstration: Allergy in Ophthalmology. Allergy in Otorhinolaryngology. Demonstration of Cases and Testing Technique. A. A. EGGERTSON, A. B. PAUL.
- 12:00-1:00. *Otolaryngology*. Operative Clinic: Tonsil Surgery. WILLIAM H. TURNLEY.
- 12:00-1:00. *Ophthalmology*. Operative Clinic: Cataract Surgery. D. H. WEBSTER.
- 10:00-11:00. *Ophthalmology*. Demonstration: Corneal Grafting Technique. Corneal Research Laboratory. R. T. PATON, H. M. KATZ.
- 12:00-1:00. *Ophthalmology*. Demonstration: Eye Pathology: Demonstration Microscopic Sections. JOSEPH LAVAL.

MEMORIAL HOSPITAL

- 8:00-10:00. *Tumor Surgery*. Operative Clinics.
- 10:00-12:00. *Tumor Surgery*. Follow-up Clinics in Cancer of the Uterus. TURNLEY.
- 3:00-4:00. *Tumor Surgery*. The Conduct of End Results in Early Cancer Detection Clinic. ELLER L. FARMSTEADT.

METROPOLITAN HOSPITAL

- 9:00-10:00. Intestinal Obstruction. CHARLES A. HALBERSTAM, ROBERT T. CROWLEY.
- 10:00-11:00. *Genitourinary Surgery*. Operative Clinic: Colon Surgery. HAROLD E. CLARK.
- Intestinal Intubation. WALTER L. MICHAELSON.

- 3:00-4:00. *Thoracic Surgery* Operative Clinic. Value of Cavemostomy in Tuberculosis (2 Operations) SAMUEL A. THOMPSON and STAFF
- 3:00-4:00. *Neurosurgery* Operative Clinic. Nerve Suture Cases. THOMAS I. HOEN, IGOR OLJENICK and STAFF

MONTEFIORE HOSPITAL

- 10:00-12:00. *General Surgery* Nonoperative Clinic. Results of Treatment of Hydrocephalus by Choroid Plexectomy. LEO DAVIDOFF
- 3:00-5:00. *General Surgery* Operative Clinic. LEO DAVIDOFF
- 3:00-5:00. *Ophthalmology* Ophthalmological Service. Vitreous Transplantation. S. GARTNER, B. PRIESTLEY. Visual Field Studies in Neurosurgery. M. CHAMLIN. Electroretinography. E. BILLET. Modified Tarsorrhaphy for High Degrees of Exophthalmos. S. GARTNER, M. CHAMLIN. Cataract Surgery in Young Diabetics. A. I. LANCHNER.

MOUNT SINAI HOSPITAL

- 8:30-10:00. *Thoracic Surgery* Operative Clinic (Surgical Amphitheatre). Operation for Patent Ductus Arteriosus. ARTHUR S. W. TOURKOFF
- 10:00-12:00. *Thoracic Surgery* Nonoperative Clinic (Surgical Amphitheatre). Intramuscular Heparin (Concentrated) Therapy in the Prevention of Post-Operative Thrombosis and Embolism. HAROLD NEUFUR. Technique of Operation for Clotted Hemothorax (Motion Picture Demonstration). Results of Operative Treatment of Traumatic Thoracic Lesions in Civilian Practice. ARTHUR S. W. TOURKOFF. Operative Results in Pediatric Surgery. ERNEST E. ARMBRIST. Results of Surgical Treatment of Perforation of the Esophagus. EDWARD A. JENGERM. Results of Conservative Surgical Treatment of Chronic Pulmonary Abscess. IRVING A. SAROT. Late Results in Pulmonary Resection for Carcinoma of the Lung.
- 3:00-5:00. *Ophthalmology* The Surgical Treatment of Glaucoma. JOSEPH LAVAL (Surgical Amphitheatre). Operative and Nonoperative Clinic (Surgical Amphitheatre). Operated Cases. HENRY MENSKY, JOSEPH LAVAL, DAVID WEXLER.

NEUROLOGICAL INSTITUTE

(See Presbyterian Hospital)

NEW YORK EYE AND EAR INFIRMARY

- 10:00-12:00. *Otolaryngology* Nonoperative Clinic. Fenestration—Preoperative and Follow-up. J. M. SMITH.
- 10:00-12:00. *Otolaryngology* Plastic Surgery Preoperative and Follow-up. JAY D. WHITMAN.
- 3:00-5:00. *Otolaryngology* Operative Clinic. Fenestration Operation. J. M. SMITH.
- 3:00-5:00. *Otolaryngology* Operative Clinic. Plastic Surgery. JAY D. WHITMAN.
- P.M.—*Ophthalmology*. Indications for Surgical Interference. KNIGHTON and ELWYN and ASSOCIATES. The Follow-up on Plastic Surgery with Discussion of Further Steps. HUGHES and COLE and ASSOCIATES. Surgical Demonstration with Emphasis on Cataract and Glaucoma Surgery. BERKINS and ROMANIK and ASSOCIATES. X Rays and Localization. SCHWARTZ.

The routine clinics of the New York Eye and Ear Infirmary will be held as usual during this period, all Fellows of the American College of Surgeons are cordially invited to attend.

NEW YORK HOSPITAL

- 9:00—*Thoracic Surgery* Operative and Nonoperative Clinic. FRANK GLENN and STAFF. Surgery of Mediastinal Tumors. WILLIAM DEW ANDRUS. Follow-up Studies of Mediastinal Tumors. JOHN ECKEL. Chronic Constrictive Pericarditis. Medical Aspects. HAROLD STEWART. Chronic Constrictive Pericarditis, Surgical Aspects. WILLIAM DEW ANDRUS. Diagnosis of Carcinoma from Disquamated Cells. GEORGE PAPANTALAO. Clinical Value of Sputum Diagnosis. HENRY CROMWELL, WILLIAM A. BARNES.
- 2:00—*General Surgery* Demonstration. Surgical Anatomy. Anatomy of Hand Involved in Infection and Trauma. ERNEST W. LAMPE.
- 3:00-4:30. *Neurosurgery* Symposium Conducted by BRONKOW S. RAY. Surgical Relief of Intractable Pain of the Head and Neck. HERBERT PARSONS. Oculographic Study of Sensory Pathways. Evidence of Bilateral Conduction. CHARLES BERRY, RICHARD KART, JOSEPH C. HINSKY. Alterations in Visceral Sensation After Thoracolumbar Sympathectomy. CHARLES L. NEILL. Induced Mechanical Stresses in the Analysis of Headache Mechanisms and the Diagnosis of Intracranial Tumors. E. CHARLES KUNKLE. Sympathetic Supply to the Lower Extremities. ARTHUR D. CONSOLE. On the Nature of Hyperalgesia. HAROLD G. WOLFF, JAMES D. HARDY, HELEN GOODRILL. Intracranial Aneurysms. BRONKOW S. RAY.
- 5:00—*Otolaryngology* Operative Clinic. Surgery of the Paranasal Sinuses. SAMUEL F. KELLY.

NEW YORK HOSPITAL

LYING-IN HOSPITAL

- A.M.—*Obstetrics and Gynecology* Operative Clinic. Total Plastic Operation for the Relief of Sterility. J. RANDOLPH GEFFERT. Gynecological Operations. R. GORDON DOUGLAS. Forceps Demonstration. JAMES A. HARRAR.
- P.M.—*Obstetrics and Gynecology* Nonoperative Clinic. Evaluation of Prophylactic Chemotherapy in Cesarean Section. R. GORDON DOUGLAS, ROBERT LANDSMAN. Labor and Delivery Following Cesarean Section. ARTHUR WILSON. Pregnancy Following Salpingostomy. J. RANDOLPH GEFFERT. Studies on Pain During Labor. CARL T. JAVERT, JAMES HARDY. The Conservative Treatment of Endometriosis. ARTHUR V. GREELEY. The Treatment of Massive Hemorrhage. JOHN T. COLE.

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL

- 8:30—*Orthopedic Surgery* Operative Clinic. ALAN DE FOREST SMITH and STAFF.
- 1:30—*Orthopedic Surgery* General Orthopedic Clinic. HALFORD HALLOCK and STAFF.

SURGERY GYNECOLOGY AND OBSTETRICS

FLOWER AND FIFTH AVENUE HOSPITALS
 9:00-10:00. A New Operation for Fibroid Cyst. JOHN
 HERRLIN. Preoperative and Postoperative Care.
 LOUIS R. KAUFMAN and WITFIELD STAFF
 10:00-11:00. Test for Viability of Bowel. JOHN HERRLIN
 KURT LAWEK, S. THOMAS OLSTER.
 Intestinal Obstruction. ROBERT T. CROWLEY
 12:00-4:00. Orthopedic Surgery. ANSON H. BINGHAM.
 Plastic Surgery. DAVID M. MYER, CLARENCE R.
 STRAUBER, JOHN F. FORD.
 Urology. SPRAGUE CARLETON and STAFF
 Teaching Exhibit in Outpatient Department.
 McGREGOR ORCHIDECTOMY. L. P. WERSHUS
 Fracture Treatment—Motion Pictures and
 End Results—Demonstrations. MILTON J. WILSON
 and STAFF

 Arterectomy. SCHMIDTKE
 Peritonitis in the Aged. CASE.
 11:30-12:00. Ward Rounds.
 2:00-4:00. *Geriatric Surgery*
 The Treatment of Varicose Ulcers by Ligation of Fem-
 oral Vein. KLEINER
 Proctitis in the Aged. DOUBILET
 Prostatectomy in the Complicated Case. BERKSTEIN.
 Interesting Urological Conditions in the Aged. SLAVUS.
 Intravenous Procaine in Surgery. OPPENHEIM.
 Arteriography. TORRESA.
 Combined Lumbar Sympathectomy and Vein Ligation
 for Peripheral Vascular Disease. SEAROWITZ
 4:30-
 Forum on Surgical Investigation by Postgrad-
 uate Class of Surgery

HARLEM EYE AND EAR HOSPITAL

8:00-9:00. *Otolaryngology* Operative Clinic—Tonsillecto-
 mies with Medial tonsil emulsor
 9:00-10:00. *Ophthalmology and Otorhinolaryngology* Oper-
 ative Clinic. Major Eye, Ear, Nose and Throat Surg-
 ery
 10:00-11:00. *Otorhinolaryngology* Demonstration Dem-
 onstration of Ear, Nose and Throat Cases
 11:00-12:00. *Otorhinolaryngology* Operative Clinic
 Rhinoplastic Surgical Cases.
 1:00-2:00. *Otorhinolaryngology* Operative Clinic. Lid
 Plastic.

HARLEM HOSPITAL

9:00-10:00. *General Surgery* Symposium on Lympho-
 glands and Rectal Structures. Ward Rounds. L.
 WEINSTEIN, J. G. LEVY and STAFF
 10:00-11:00. *Gynecology* Symposium. H. C. FALK, P. M.
 MURRAY, and STAFF
 Operative Clinic in Gynecological Surgery
 Nonoperative Clinics (a) Management of Postabortal
 Infection (b) Management of Recurrent Salpingitis
 (c) Management of Pyosalpinx Complicating Fibroid
 with End-Results.

HOSPITAL FOR JOINT DISEASES

9:00-10:00. *Orthopedic Surgery* Operative Clinic. Nerve
 Resection for Painful Arthritis of Hip Joint. ISADORE
 ZADEK.

Surgical Anatomy. Mechanism of Motion of Throat
 EMANUEL KAPLAN
 12:00-4:00. *Genitourinary Surgery* Operative Clinic. Hem-
 orrhoids. Fistulas—Anal. Benign Adenoma of Rectum
 Fibroid Cyst. Nonoperative Clinic. Lymphogranu-
 loma Venereum. HARRY GOLDMAN.
 1:00-4:00. *Genitourinary Surgery* Operative Clinic. Sur-
 gery of the Kidneys, Ureter and Bladder. PAUL ANCH-
 WER.
 10:00-12:00. *Plastic Surgery* Operative Clinic. Rhinoplasty
 Follow-up Clinic. Nasal, Lip and Face Plastics. LEO
 GOLDENBAUM.

HOSPITAL FOR SPECIAL SURGERY

8:30-10:00. *Orthopedic Surgery* Operative Clinic. Chil-
 dren Service.
 10:00-11:00. *General Surgical Problems*. BRENNAN GRACE,
 COLLEY and STAFF
 10:00-5:00. *General Surgical Problems and Plastic Surgery*

LYING-IN HOSPITAL (See New York Hospital)

MANHATTAN EYE, EAR AND THROAT HOSPITAL

9:00-
 Clinic. A. LINTAS.
 10:00-
Ophthalmology Demonstration of Anisokonia
 Operations of Eye. BYRON SMITH.
 10:00-
Otolaryngology Demonstration Postopera-
 tive Cases. M. F. JONES, R. J. BULLOCK.
 9:30-
 Clinic. KOCKE.
 Late Results of Glaucoma Surgery. F. L. P.
 10:00-
Ophthalmology Demonstration. Corneal
 Grafting Techniques on Rabbits. H. M. KATZ.
 10:00-
Otorhinolaryngology Operative Clinic and
 Demonstration. Operation for Polypoid Sinusitis and
 Demonstration of Postoperative Cases. A. NORD-
 11:30-
Otolaryngology Bronchoscope Clinic: Diag-
 nosis and Treatment. D. S. COHEN.
 12:00-
Otolaryngology Operative Clinic: Prostati-
 tion Operation. M. F. JONES.
 10:00-
Ophthalmology and Otorhinolaryngology Dem-
 onstration. Allergy in Ophthalmology. Allergy in
 Otorhinolaryngology. Demonstration of Cases and
 Testing Techniques. A. A. EMMETT, A. B. PAUL.
 1:00-
Otolaryngology Operative Clinic: Tonsil-
 Surgery. WILLIAM H. TOWSE.
 12:00-
Ophthalmology Operative Clinic: Cataract
 Surgery. D. H. WERTZ.
 12:00-
Ophthalmology Demonstration. Corneal
 Grafting Techniques. Corneal Research Laboratory.
 R. T. PATON, H. M. KATZ.
 3:00-
Ophthalmology Demonstration. Eye Path-
 ology. Demonstration Microscopic Sections. JONES
 LAVAL.

MEMORIAL HOSPITAL

8:00-10:00. *Tumor Surgery* Operative Clinics.
 10:00-12:00. *Tumor Surgery* Follow-up Clinics in Cancer of
 the Uterus. TOWNLEY
 3:00-4:00. *Tumor Surgery*. The Conduct of End Results
 in Early Cancer Detection Clinic. ELLIS L. FARMER.

METROPOLITAN HOSPITAL

9:00-10:00. Intestinal Obstruction. CHARLES A. HALLER
 STAM, ROBERT T. CROWLEY
 10:00-11:00. *Genitourinary Surgery* Operative Clinic:
 Colon Surgery. HAROLD E. CLARK.
 Intestinal Intubation. WALTER L. MONTGOMERY.

- 2:00-4:00. *Thoracic Surgery* Operative Clinic Value of Cavernostomy in Tuberculosis (2 Operations) SAMUEL A. THOMPSON and STAFF
- 2:00-4:00. *Neurosurgery* Operative Clinic Nerve Suture Cases. THOMAS I. HOWE, IGOR OLJENETSK and STAFF

MONTEFIORE HOSPITAL

- 10:00-12:00. *General Surgery* Nonoperative Clinic: Results of Treatment of Hydrocephalus by Choroid Plexectomy LEO DAVIDOFF
- 2:00-3:00. *General Surgery* Operative Clinic. LEO DAVIDOFF
- 3:00-5:00. *Ophthalmology* Ophthalmological Service Vitreous Transplantation. S. GARTNER, B. PRITZLEY Visual Field Studies in Neurosurgery M. CREAMLIN Electroretinography E. BILLET Modified Tansoraphy for High Degrees of Exophthalmos S. GARTNER, M. CREAMLIN Cataract Surgery in Young Diabetics. A. I. LANCINGER

MOUNT SINAI HOSPITAL

- 8:30-10:00. *Thoracic Surgery* Operative Clinic (Surgical Amphitheatre) Operation for Patent Ductus Arteriosus. ARTHUR S. W. TOUROFF
- 10:00-12:00. *Thoracic Surgery* Nonoperative Clinic (Surgical Amphitheatre) Intramuscular Heparin (Concentrated) Therapy in the Prevention of Post-Operative Thrombosis and Embolism. HAROLD NEUBOF Technique of Operation for Clotted Hemothorax (Motion Picture Demonstration) Results of Operative Treatment of Traumatic Thoracic Lesions in Civilian Practice. ARTHUR S. W. TOUROFF Operative Results in Pediatric Surgery. ERNEST E. AKERHED Results of Surgical Treatment of Perforation of the Esophagus. EDWARD A. JEWERLIN Results of Conservative Surgical Treatment of Chronic Pulmonary Abscess. IRVING A. SAROT Late Results in Pulmonary Resection for Carcinoma of the Lung.
- 2:00-5:00. *Ophthalmology* The Surgical Treatment of Glaucoma. JOSEPH LAVAL (Surgical Amphitheatre) Operative and Nonoperative Clinic (Surgical Amphitheatre) Operated Cases. HENRY MINOFF, JOSEPH LAVAL, DAVID WEXLER.

NEUROLOGICAL INSTITUTE

(See Presbyterian Hospital)

NEW YORK EYE AND EAR INFIRMARY

- 10:00-12:00. *Otolaryngology* Nonoperative Clinic Fenestration—Preoperative and Follow up. J. M. SMITH
- 10:00-12:00. *Otolaryngology* Plastic Surgery Preoperative and Follow-up. JAY D. WHITMAN
- 2:00-5:00. *Otolaryngology* Operative Clinic Fenestration Operation J. M. SMITH
- 2:00-5:00. *Otolaryngology* Operative Clinic Plastic Surgery JAY D. WHITMAN
- P.M.—*Ophthalmology* Indications for Surgical Interference. KIRKSTON and ELWIN and ASSOCIATES. The Follow-up on Plastic Surgery with Discussion of Further Steps. HUGHES and COLE and ASSOCIATES. Surgical Demonstration with Emphasis on Cataract and Glaucoma Surgery. BERENS and ROMADNE and ASSOCIATES. X Rays and Localization. SCHWARTZ.

The routine clinics of the New York Eye and Ear Infirmary will be held as usual during this period, all Fellows of the American College of Surgeons are cordially invited to attend.

NEW YORK HOSPITAL

- 9:00—*Thoracic Surgery* Operative and Nonoperative Clinic. FRANK GLENN and STAFF
- Surgery of Mediastinal Tumors. WILLIAM DEW ANDRU
- Follow up Studies of Mediastinal Tumors. JOHN ECKEL
- Chronic Constrictive Pericarditis Medical Aspects HAROLD STEWART
- Chronic Constrictive Pericarditis, Surgical Aspects. WILLIAM DEW ANDRU
- Diagnosis of Carcinoma from Disquamated Cells. GEORGE PAPANICOLAOU
- Clinical Value of Sputum Diagnosis. HENRY CROW WELLS, WILLIAM A. BARNES
- 2:00—*General Surgery* Demonstration Surgical Anatomy Anatomy of Hand Involved in Infection and Trauma. ERNEST W. LAMPE
- 2:00-4:30. *Neurosurgery* Symposium Conducted by BROOKS S. RAY
- Surgical Relief of Intractable Pain of the Head and Neck. HERBERT PARSONS
- Oscillographic Study of Sensory Pathways Evidence of Bilateral Conduction CHARLES BERRY RICHARD KARL, JOSEPH C. HINSEY
- Alterations in Visceral Sensation After Thoracolumbar Sympathectomy CHARLES L. NEILL
- Induced Mechanical Stresses in the Analysis of Head ache Mechanisms and the Diagnosis of Intracranial Tumors. E. CHARLES KUNDEL
- Sympathetic Supply to the Lower Extremities. ARTHUR D. CONSOLE On the Nature of Hyperalgesia. HAROLD G. WOLFF, JAMES D. HARDY, HELEN GOODSELL
- Intracranial Aneurysms. BROOKS S. RAY
- 2:00—*Otolaryngology* Operative Clinic Surgery of the Paranasal Sinuses. SAMUEL F. KELLY

NEW YORK HOSPITAL

LYING-IN HOSPITAL

- A.M.—*Obstetrics and Gynecology* Operative Clinic Tubal Plastic Operation for the Relief of Sterility J. RANDOLPH GIFFERT
- Gynecological Operations. R. GORDON DOUGLAS. Forceps Demonstration. JAMES A. HARRAL
- P.M.—*Obstetrics and Gynecology* Nonoperative Clinic Evaluation of Prophylactic Chemotherapy in Cesarean Section R. GORDON DOUGLAS, ROBERT LANDESMAN Labor and Delivery Following Cesarean Section ARTHUR WILSON
- Pregnancy Following Salpingostomy J. RANDOLPH GIFFERT
- Studies on Pain During Labor CARL T. JAVERT, JAMES HARDY
- The Conservative Treatment of Endometriosis. ARTHUR V. GRIELEY
- The Treatment of Massive Hemorrhage. JOHN T. COLE

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL

- 8:30—*Orthopedic Surgery* Operative Clinic ALAN DE FOREST SMITH and STAFF
- 1:30—*Orthopedic Surgery* General Orthopedic Clinic HALFORD HALLOCK and STAFF

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL

- 9:00-12:00. *Neurosurgery* Operative Clinic (Amphitheatre, 6th Floor) Follow-up Clinic (Erdmann Auditorium) Patient Illustration.
- 11:00-12:00. *General Surgery* Value of Immediate and Delayed Cholangiography in the Surgical Management of Common Duct Disease Case Illustration (Erdmann Auditorium)
- 12:00-1:00. *General Surgery* Nonoperative Clinic (Erdmann Auditorium) Follow-up Results in Advanced Common Bile Duct Lesions. Case Illustration.
- 1:00-5:00. *General Surgery* Operative Clinic (Amphitheatre, 6th Floor)

PRESBYTERIAN HOSPITAL

- 8:00- *General Surgery* Operative Clinic Surgery of the Breast. CURRIEMAN D. HAAGENBOOM and STAFF
- Surgery of the Stomach. RICHARD N. SCHULLINGER, EDWARD L. HOWES, HAROLD D. HARVEY
- 12:00-4:00. *General Surgery* Nonoperative Clinic Certain Essential Features Suggested by 30 Year Follow-up in Carcinoma of the Breast. HILTON ARTHURSON
- The Relation of Chronic Cystic Disease to Carcinoma of the Breast. ARTHUR PERCY SPOTT
- The Problem of Early Diagnosis in Carcinoma of the Breast. CURRIEMAN D. HAAGENBOOM
- Röntgenotherapy of Carcinoma of the Breast in Non-operated Cases and as Preoperative and Postoperative Treatment. MAURICE LORZ
- Surgery Versus Radiation in Carcinoma of the Breast. CURRIEMAN D. HAAGENBOOM

PRESBYTERIAN HOSPITAL BABIES HOSPITAL

- 9:00- *General Surgery* Operative Clinic. STAFF OF THE STAFF
- 11:00- *General Surgery* The Surgical Treatment of Cyanotic Heart Disease. GEORGE H. HENRIKSEN
- 1:00- *General Surgery* Nonoperative Clinic
- Röntgen Findings in Intestinal Obstruction of the Newborn. JOHN CAVY
- Treatment of Acute Hematogenous Osteomyelitis. Comparison of Cases Treated with and without Penicillin. Follow-up. EDWARD B. SELBY
- End Results of Operations for Undescended Testicle. EDWARD N. GOODMAN
- Infantal Hernia in Infancy and Childhood. Indication for Operation. Infancy Follow-up. JOHN M. FRANK

PRESBYTERIAN HOSPITAL NEUROLOGICAL INSTITUTE

- 9:00-12:00. *Neurosurgery* Operative Clinic Cases Pre-viously Shown Clinically at the Tuesday Morning Staff Conference.

PRESBYTERIAN HOSPITAL THE INSTITUTE OF OPHTHALMOLOGY

- 9:00-12:00. *Ophthalmology* Nonoperative Clinics: External Diseases of the Eye. JOHN HUGHES DEWEES and STAFF
- 1:00- *Ophthalmology* Operative Clinic Surgery of the Extraocular Muscles and Intracocular Operations. JOHN HUGHES DEWEES
- Surgical Procedures in Glaucoma and Cataract. ALGER HORN BEVERLY REESE and STAFF

PRESBYTERIAN HOSPITAL SECTION OF OTOLARYNGOLOGY

- 9:00-12:00. *Otolaryngology* Nonoperative Clinic: Hearing Aid Fitting. MILLERED SCHOEN
- 12:00-1:00. *Otolaryngology* Operative Clinic: Endoscopy
- 1:00-5:00. *Otolaryngology* Operative Clinic: Endoscopy
- GEORGE BRIGHTON
- FRANKLIN WOODMAN

PRESBYTERIAN HOSPITAL SLOAN HOSPITAL FOR WOMEN

- 9:00- *Gynecology and Gynecology* Operative Clinic: Repair of Cystocele, Rectocele and Pelvic Floor. B. P. WATSON
- 1:00- *Gynecology and Gynecology* Operative Clinic: Operation for Vesical Incontinence. JOHN H. BORN
- 3:00- *Gynecology and Gynecology* Nonoperative Clinic: Surgical Problems in Sterility. C. L. BERTON
- 5:00- *Gynecology and Gynecology* Nonoperative Clinic: Endocrine Activation of Uterine Tumors. E. T. EAGLE
- 7:00- *Gynecology and Gynecology* Nonoperative Clinic: The Possible Carcinogenic Effect of Estrogens. S. GUY PRO

PRESBYTERIAN HOSPITAL SOLTER UROLOGICAL CLINIC

- 9:00-12:00. *Urology* Nonoperative Clinic: Sclerosing Milium in the Treatment of Genito-Urinary Disease. J. H. BENTON
- The Study of the Effect of Streptomycin on Renal Tuberculosis. Preliminary Report. JOHN K. LATTIMER
- Pathological Classifications of Adrenal Tumors. MARY M. MILLER
- Problems Encountered in the Diagnosis and Treatment of Congenital Anomalies of the Urinary Tract in Infants. JOHN V. RODRIGUEZ, CHARLES T. HAZARD
- 1:00-4:00. *Urology* Operative Clinic: Surgical Operations. GEORGE F. CARRILL and STAFF

PRESBYTERIAN NEW YORK ORTHOPEDIC HOSPITALS

- 9:00-12:00. *Fractures and Traumatic Surgery* Operative Clinic. CLAY RAY McBRAT and STAFF
- 12:00-4:00. *Fractures and Traumatic Surgery* Nonoperative Clinic: Shoulder Clavicle Injuries and Recurrent Shoulder Dislocations. Follow-up Results. H. S. McBRAT
- Results of Open and Closed Treatment of Potts Fractures. B. S. McBRAT

ROOSEVELT HOSPITAL

- 9:00- *General Surgery* Operative Clinic: Cancer of the Breast
- Radical Mastectomy: Results, Presentation of Cases and Illustration. Late Results. WILLIAM C. WHITE and STAFF
- 1:00- *General Surgery* Nonoperative Clinic: The Late Results of Carcinoma of the Thyroid Gland. JAMES E. THOMPSON
- Presentation of Cases Illustrating Interesting and Unusual Fractures. (Illustrations). WILLIAM H. CASE
- Nonunion in Fractures of the Femoral Neck, Case Presentations (Illustrations). M. BECKETT HOWARTH

ST LUKE'S HOSPITAL

- 8:30-1:00. *Genitourinary Surgery* Operative Clinic
GEORGE HOCH and STAFF
- 11:00-1:00. *Orthopedic Surgery* Clinical Demonstration
Pathological Demonstration of Internal Derangement
of Knee Joint with End Results. DAVID BOWWORTH,
EDWARD WINANT
- Trochanteric Fractures of Femur Treatment and End
Results. FRED THOMPSON
- Intracapsular Fractures of Femur Treatment and End
Results. MATTHEW CLEVELAND.
- 2:00-5:00. *Genitourinary Surgery* Clinical Demonstra-
tions Follow-up on War Paraplegics. BORIS PETROFF
- Follow-up on Renal Tumors. JOHN TAYLOR.
- Follow-up on Vesical Neck Obstructions to Abdomino-
perineal Resection. JAMES WAUGH
- Results of Transurethral Resection GEORGE HOCH
(presented by C. H. PLACK)
- Combined Treatment of Transvesical Resection and Ra-
diotherapy of Bladder Tumors. E. CRAIG COATES.
- Renal Rickets. ALLEY
- Bilateral Hydronephrosis and Hydroureter GEORGE
HOCH.

ST VINCENT'S HOSPITAL

- 9:00- *General Surgery* Operative and Nonoperative
Clinic Surgery of Gastric and Duodenal Ulcer
GEORGE R. STUART FRANK J. MCGOWAN J. P.
BRUCKNER.
- 9:00- *General Surgery* Operative Clinic RAYMOND
P. SULLIVAN and ASSOCIATES.
- 9:00- *Neurosurgery* Operative Clinic and Follow-up
Study of the Treatment of Painful Phantom Limb
by Removal of Sensory Cortex. C. G. DE GUTTEREZ
MABONEY
- 2:00- *General Surgery* Round Table Discussion
Acute Pancreatitis. CONSTANCE J. MAQUETRE.
- Reconstruction of Common Bile Duct. RAYMOND P.
SULLIVAN JOHN C. MURPHY
- Follow-up Report on 100 Cases of Fracture of Both
Bones of the Legs. EDWARD V. DENKIN E. R.
EASTON

- 2:00- *Pathology Tissue Culture* Demonstration of
Malignancy Display of Fresh Pathological Material.
Display and Demonstration of System Diseases by
Kodachrome Slides. A. ROTTINO and ASSOCIATES

SLOANE HOSPITAL FOR WOMEN

(See Presbyterian Hospital)

VETERANS ADMINISTRATION HOSPITAL

- 9:00- *General Surgery* Operative Clinic. JOHN E.
SULLIVAN CARLES WEEKS.
- 9:00- *Thoracic Surgery* Operative Clinic. RICHMOND
MOORE, WALTER CRANDALL, AARON HIMMELSTEIN
- 9:00- *Vascular Surgery* Operative Clinic. ERNEST
KRUEGER, FITZ CRAMER.
- 9:00- *Plastic Surgery* Operative Clinic. CLARENCE
R. STRAATMAN, ROBERT CLIFFORD.
- 9:00- *Otorhinolaryngology* Operative Clinic. HENRY
THALER.
- 9:00- *Radiology* Radiotherapy Lymphomas and
Leukemia. BERNARD ROSEWITZ
- 9:30-11:30-Medical Rehabilitation Clinic—Demonstrations.
HARRY KESLER, KARL HARPODER, IRWIN D. STEIN
BERNARD STOLL, JACOB BYER.
- 11:00- *General Surgery* Nonoperative Clinic Cardi-
noma of Pancreas. J. E. SULLIVAN
- 1:30- *Thoracic Surgery* Conference. FRANK BERRY
RICHMOND MOORE, WALTER CRANDALL, AARON HIM-
MELSTEIN and RESIDENT STAFF
- 3:30- *General Surgery* Combined Medico-Chirurgi-
cal Differential Diagnosis of Medical and Surgical
Jaundice. FRANKLIN M. HANOVER, ALLEN O. WHIFFLE
FREDERIC W. BANCROFT, BERNARD STRAUSS, CHARLES
A. FLOOD, JOSEPH POST

CLINICS IN BROOKLYN—LONG ISLAND HOSPITALS

Wednesday

BROOKLYN EYE AND EAR HOSPITAL

- 1 M *Ophthalmology* Operative Clinic.
- P M *Ophthalmology and Otolaryngology* Nonopera-
tive Clinic Late Results in Detachment of Retina
Late Results in Cataract Extraction Late Results in
Fenestration Late Results in Dacryocystorhinostomy
Late Results in Ptosis. Motion Picture Demonstration
in Color on Basic Anatomy of the Visual Pathway as
Shown by Animation and Dissection.

CUMBERLAND HOSPITAL

- 9:00-12:30. *General Surgery* Operative Clinic. Gastrecto-
my for Cancer of the Stomach with Discussion of Late
Results. JOHN J. GAINKY and STAFF
- Ward Rounds with Discussion of Surgical Gall Bladder
with Late Results. JOHN A. THOM and STAFF
- Ward Rounds with Discussion of Surgery in Large Bowel
Malignancy. HOWARD T. BLATT.
- Retropertitoneal Teratoma with Slides
- 2:00-5:00. Arteriovenous Fistula. JOSEPH L. ANTON

- Lymphogranuloma Inguinale (Venereum) of Uterus.
Follow-up. SILEX H. POLATZ.
- Thoracic Surgery in General Hospital. WILLIAM H.
FIELD.
- Common Duct Atresia. JOHN A. THOM.
- Congenital Esophageal Atresia. SAUL F. LIVINGSTON
- Traumatic Evisceration with Follow-up. MARTIN LUTZ.

JEWISH HOSPITAL

- 8:00-10:00. *General Surgery* Operative Clinic. HENRY
LOURIA and STAFF and RUDOLPH NISSEN and STAFF
- 10:00-12:00. *General Surgery* Nonoperative Clinic: Culture
and Endotracheal Anesthesia in Poor Risk Patients.
IRVING M. PALLIN.
- Treatment of Postoperative Phlebotrombosis with Sub-
cutaneous Heparin. EDWARD HIRSCH, LEO LOWE.
- Bleeding Nipple. SAUL F. LIVINGSTON.
- Acute Mediastinitis. LEW A. HORNBERG.
- Endorhaphy as Surgical Procedure in the Treatment of
Giant Air Cysts of the Lung. RUDOLPH NISSEN

SURGERY GYNECOLOGY AND OBSTETRICS

External Ophthalmoplegia Associated with Hyperthyroidism. VICTOR WOLOVY
The Diagnosis and Surgical Treatment of Thyroiditis. ARTHUR A. WOLVING

Malignant Tumors of the Thyroid Gland Diagnosis, Management and End-Results. FRANK TELLER
Surgical Management of Goiter. HENRY W. LOVIE
General Surgery. Nonoperative Clinic. T. A. UN
Early Dysphagia of the Hip. Diagnosis and Treatment. M. T. KORYN
The Conservative Management of Slipping of the Upper Femoral Epiphysis. L. S. NELSON
The Use of the Austin Moore Plate and Its Modifications in High Osteotomy of the Femur. B. KOVNER
Reconstruction Key Gliding Mechanism of Upper Extremity. JOSEPH E. MILLER
Composition of Bone in Relation to Blood and Diet. A. E. SOMER
The Application of Laminography to Some Orthopedic Problems. B. S. EPPSTEIN

KINGS COUNTY HOSPITAL

9:00-1:00. Plastic Surgery. Operative Clinics. Cleft Palate. SKIN Graft of Burns. WALTER COCKLEY and Staff
9:00-1:00. Plastic Surgery. Nonoperative Clinic. Presentation of Cases, Ward Walk.
Acute Burns (Lye, Acid, Hot Water Electricity and Fire)
Hump and Saddle Noses
Cleft Lip and Palate
Contracted Scars
Web Fingers
Hemangiomas and Lymphangiomas (Lip)
Jug handle Ears
Depressed Fractures—(a) of Malar Bone (b) of Zygomatic Processes (c) of Infraorbital Ridge (d) Fractures of Mandible with and without Loss of Substance (e) Fractures of Superior Maxilla
Skin Grafts—(1) Split-skin, (2) Tube Grafts
Exhibition of Mouldings Photographs and X-rays of Facial Bone Fractures
Animated Motion Pictures Reconstruction Surgery of the Bones of the Face Cleft Palate Operation
1:00- Plastic Surgery Presentations WALTER COCKLEY
LEY
Experiences in the Treatment of 500 Severe Burns
WALTER COCKLEY
Results of Skin-Grafting in Chronic Leg Ulcers. D. VID
TAPPELEY
Skin-Grafting of Burns JOSEPH CALTAGIRONY
Plastic Procedures

LONG ISLAND COLLEGE HOSPITAL

9:00-1:00. General Surgery. Operative Clinics. Thyroidectomy and Other Procedures. EMIL GOETZMAN and Staff
Chronic Thyroiditis. EMIL GOETZMAN
Role of Thyroidectomy in the Preparation of the Critically Ill Hyperthyroid Patient. ARTHUR GOETZMAN
The Presumptive Case as a Problem in Thyroid Surgery. JAMES J. RUTENBERG
Surgical Treatment of Colon Carcinoma. BENJAMIN CLARKE
Radical Mastectomy for Breast Malignancy—Rodman's Method. GUSTAVO DEL VAL
Spontaneous Rupture of Bile Ducts Following Cholecystectomy

Postoperative Management of Thoracic Surgery Patients. F. K. JONKOV
Externalization of the Pericardial Region for Obstructing Lesions in Infants and Children. ROBERT MARCHEL
(The Departments of Ophthalmology and Otolaryngology will conduct their programs at the Brooklyn Eye and Ear Hospital)

METHODIST HOSPITAL

8:00-1:00. General Surgery. Operative Clinic. DR. H. A. REYNOLDS
General Surgery. Operative Clinic. HOWARD T. LIVINGSTON and Staff
9:00-5:00. Symposium on General Surgery and Specialties
Surgery of the Gastrointestinal Tract in the Newborn. C. D. SWEET
The Meyers Operation for Inguinal Hernia. E. MARTIN

Hyperpyrexia in Surgery. A. LOEBEL
Management of Acute Cholecystitis. H. F. GRAHAM
Acute Pancreatitis—A Ten Year Survey. M. CANNON
Supracondylar Fractures of Humerus. H. P. LARSEN
Follow-up on Unusual Genitourinary Cases. H. T. LAWRENCE
Tuberculosis of the Kidney. R. MITCHELL
Care of Genitourinary Tract in Paraplegia. O. P. SCHROEDER
Thoracoabdominal Injuries. E. MARTINOV
Demonstration of Pathology. J. HOFFER
Demonstration of X-rays. G. W. CHASE

ST. JOHN'S HOSPITAL

9:00-1:00. General Surgery. Operative Clinic. Thyroidectomy. Toxic Diffuse Goiter. Patient Prepared for Prophylactic Subtotal Gastric Resection for Duodenal Ulcer
8:00-1:00. Gynecology. Operative Clinic. Manchester Pothrell Operation. Vaginal Hysterectomy
9:00-5:00. Nonoperative Clinic
Demonstration of Unusual X-ray Findings and Problems in Diagnosis—Informal Discussion
Demonstration of Unusual Gross Pathological Specimens—Informal Discussion
Ward Rounds—Gynecology
Surgery of the Hand, Gastrointestinal Surgery
Orthopedic Surgery
Luncheon in the Main Dining Room as Guests of the Hospital
10:40-11:00. Round Table Discussion
The Present Status of Prophylactic Use in Toxic Goiter
MICHAEL N. FOOT
Open Surgery Resection for Carcinoma of the Duodenum
the Bladder as a Treatment of Choice—End-Results
A. HARRIS
The Clinical Application of Cardiopulmonary Physiology in Thoracic Surgery. ELIOT JONKOV
Evaluation of Therapeutic and Diagnostic Para-aortic Block
Vascular Diseases of the Extremities. LEO WATTS
Surgical Lesions of the Hand. Follow up Results. GEORGE B. RUTZ
(1) Postpartum Eclampsia Associated with Hydatidiform Mole—End-Results (2) Geriatric Nephroblastoma—End-Results (3) Geriatric Nephroblastoma—End-Results. CHARLES MITCHELL
ROBERT WARREN ARTHUR MITCHELL
The Value of Detergent (Arumol O.T.) in Antiseptic Therapy. E. J. GRACE

CLINICS IN NEW YORK HOSPITALS

Thursday

BABIES HOSPITAL
(See Presbyterian Hospital)

BELLEVUE HOSPITAL—FIRST

(COLUMBIA UNIVERSITY) SURGICAL DIVISION
8:00—12:00. *Thoracic Surgery* Operative Clinic. (Operating Rooms C and D 5th floor) FRANK B. BERRY and STAFF

2:00—4:30. *Thoracic Surgery* Nonoperative Clinic (I & K Building, Stewart Amphitheatre) FRANK B. BERRY and STAFF

Supportive Diseases of the Lung. WALTER B. CRANDALL.
Cardiopulmonary Physiology. RICHARD RILEY AARON HINDOLSTEN

Surgery of Tuberculosis. JOHN MAXWELL CHAMBERLAIN
Surgical Treatment of Chronic Spontaneous Pneumothorax. HERBERT C. MAIER

Carcinoma of the Lung. ADRIAN LAMBERT

BELLEVUE HOSPITAL—THIRD (NEW YORK UNIVERSITY) SURGICAL DIVISION

8:00—10:00. *General Surgery* Operative Clinics (Operating Rooms K 3 and K-6 Psychiatric Surgical Operating Room) JOHN H. MULLIGAN and STAFF

Thyroidectomy. JOHN A. LAWLER (Operating Room A)
Anterior Resection of the Rectum for Carcinoma. SAMUEL STANDARD (Operating Room B)

Section of Splincter of Oddi for Pancreatitis. JOHN MULLIGAN, HENRY DOUBILET (Operating Room C)
Lumbar Sympathectomy for Peripheral Vascular Disease. WALLACE B. MURPHY (Operating Room D)

Murray-Brackett Osteotomy for Unilateral Fracture of Neck of Femur. IRWIN S. SMITH (Bone Room K-6)
Bope Graft for Ununited Fracture of Tibia. IRWIN S. SMITH (Bone Room K-6)

Thoracolumbar Sympathectomy for Hypertension. HIRSHY M. WEINSTEIN (Psychiatric Surgical Operating Room 7)

10:30—1:00. *General Surgery* Nonoperative Clinics (I & K Building, Stewart Amphitheatre)
Results of Section of Splincter of Oddi for Pancreatitis. HENRY DOUBILET

Role of Sulfadiazine in Thyrotoxic Patients. JOHN A. LAWLER

Results and Follow-up in Carcinoma of the Rectum Treated with Anterior Resection. SAMUEL STANDARD

Pulmonary Complications in Surgery. WALTER CRANDELL

Fluid Compartments in Depleted Surgical Patients and Changes During Repletion. CO. TUL

General Principles of Reconstructive Plastic Surgery of the Face. JOHN M. CONVERSE

Program of Postgraduate Training in Surgery at New York University College of Medicine. JOHN H. MULLIGAN

A.B.L. *Radiology*—Demonstrations (I & K Building, Ground Floor) Treatment of Carcinoma of the Cervix. ISA I. KAPLAN and STAFF

8:00—12:00. *Anesthesia*. Demonstration (C & D Operating Rooms, 5th Floor C & D Building) Anesthesia in Thoracic Surgery. E. A. ROSENBERG and STAFF

8:30—12:00. *Gynecology* Operative Clinic. WILLIAM E. STURGEON and STAFF (K-6 Operating Room)
Total Hysterectomy for Fibroid. CLAUDE E. HEATON

Unusual Cases of Dysmenorrhea in Young Women—A Report of 3 Cases (paper)

Fascial Transplant for Relief of Stress Incontinence in Patients with Previous Operations. WILLIAM E. STURGEON

9:00—10:00. *Radiology* Roentgen Demonstrations of Surgical Diseases. LEWIS J. FRIEDMAN and STAFF (I & K Building, Ground Floor)

Surgical Lesions of the Small Bowel Roentgenologically Considered. J. BUCKSTEIN

Surgical Problems of the Chest. P. STRAUSS
Diagnostic Problems in Osseous Disease. M. ZURROW

Diagnosis of Renal Surgical Disease. H. ZUKERMAN
Interesting Neurosurgical Cases. LEWIS J. FRIEDMAN

HERBERT LONCE
9:00—10:00. *Otorhinolaryngology* Operative Clinic (K-6 Operating Room) Laryngeal Surgery. JOHN F. DALY and STAFF

9:00—10:00. *Anesthesia*. Demonstrations (K-6 Operating Rooms) Therapeutic Nerve Block Clinic. Anesthesia and Shock. E. A. ROSENBERG and STAFF

BETH ISRAEL HOSPITAL

9:00—12:00. *Gynecology* Operative and Nonoperative Clinic. HENRY FALK and STAFF

9:00—10:00. *Anesthesia*. Clinical Demonstrations—Film on Hemorrhage and Shock. S. G. HENSHAW and STAFF

FLOWER AND FIFTH AVENUE HOSPITALS

9:00—11:00. *Anesthesiology* Lumbar Sympathectomy—Technique of Block. S. THOMAS GLASSER. DONALD E. BRACE

11:00—12:00. Hand Infections. JAMES M. WINFIELD, JOHN HERRLIN

General Surgery Diseases of Vascular System. FREDERIC W. BANCROFT

9:00—10:00. Exhibit of Postgraduate School—Regional Iliitis. JOSEPH H. FOWLER

9:00—10:00. Functional Concept of the Internal Ring—Surgical Application in the Repair of Inguinal Hernia—Operating Room or Cadaver. J. CLIFFORD HAYNER

HARLEM HOSPITAL

9:00—12:00. *Trauma Symposium* Ward Rounds. L. T. WRIGHT

Head and Neck Injuries. D. H. SMITH, J. GREENE, S. SHEDDEN

Fractures of the Extremities with Late Results. A. C. LOGAN, W. A. FREEMAN, A. PRIVITERA, C. DI LORINGO

9:00—10:00. *Obstetrical Symposium*. Obstetrical Emergencies. Toxicemia of Pregnancy. F. A. KASDENHORN, A. C. POSNER, J. KURLOCK, M. SCHREIBER, N. PLECHETTE

HOSPITAL FOR JOINT DISEASES

9:00—12:00. *Orthopedic Surgery* Operative Clinic. HARRY SONENSHINE and STAFF

Transcervical Osteotomy for Slipped Femoral Epiphysis. A. KENIG

Femoral Shortening for Inequality of Leg Length. B. J. MINTZ

Nonoperative Clinic Transcervical Osteotomy. A. KENIG

Equalization of Leg Length. B. J. MINTZ
Tendon Transplantation for Radial Nerve Paralysis. H. ALTMAN

- Curvilinear Osteotomy C. SORELL.
 1:00-1:20. *Orthopedic Surgery* Demonstration X Rays of Primary Bone Tumors. MAURICE POMERANCE.
 1:20-1:40. *Ophthalmology* Operative Clinic. Operations in the Eye. JAMES W. SMITH.

HOSPITAL FOR SPECIAL SURGERY

- 8:30-12:00. *General Surgery* Operative Clinic.
 9:00-1:00. *Orthopedic Surgery* Adult Orthopedic Problems.
 1:00-1:20. *Orthopedic Surgery*. Operative and Nonoperative Clinic—Hip Problems.
 Treatment of Fractures of Femoral Neck in the Aged. FREDERICK VON SAAL.
 Trochanteric Arthroplasty. PHILIP D. WILSON.
 Transplantation of External Oblique for Paralysis of Hip Abductors. LOWELL THOMAS, T. CAMPBELL.
 THOMPSON, L. RADWAY STRAUER.
 Treatment of Congenital Dislocation of the Hip with Anterior. FRANCIS CARR.
 Idiopathic Aseptic Necrosis of the Hip in Adults. WILLIAM COOPER.

LYING-IN HOSPITAL

(See New York Hospital)

MANHATTAN EYE, EAR AND THROAT HOSPITAL

- 9:00-1:00. *Ophthalmology*. Operative Clinic. Cataract Extraction, Corneal Transplant. Dacryocystorhinostomy. G. BONACCIOLO.
 9:00-1:00. *Ophthalmology*. Laboratory Demonstration. Bacteriology of the Eye. F. C. KILL, JR.
 9:00-1:00. *Otolaryngology*. Demonstration. Results in Cases of Arytenoidectomy. J. D. KELLY.
 9:00-1:00. *Ophthalmology and Otolaryngology*. Plastic Surgery Clinic. Conference on End-Results. Lantern Slides and Motion Pictures. J. M. CONVERSE, BYRON SMITH.
 1:00-1:20. *Ophthalmology and Otolaryngology*. Operative Clinic. Plastic Surgery. BYRON SMITH, J. M. CONVERSE.
 1:20-1:40. *Ophthalmology*. Operative Clinic. Corneal Graft. R. T. PATON.
 1:40-2:00. *Ophthalmology*. Demonstration. Vitreous Substitution, Technique and End Results. MARIO FRIZZ.
 2:00-2:20. *Ophthalmology and Otolaryngology*. Radiology Clinic. Radiotherapy in Ophthalmology. Results of Radiation in Laryngeal Tumors. MAURICE LEXER, J. R. FREED, C. OVERADOTT.
 2:20-2:40. *Otolaryngology*. Demonstration. Radiation of Hypertrophied Lymphoid Tissue of Nasopharynx. H. D. TATUM.
 2:40-3:00. *Otolaryngology*. Operative Clinic. Arytenoidectomy Operation. J. D. KELLY.
 3:00-3:20. *Ophthalmology*. Demonstration. Postoperative Corneal Graft Cases. R. T. PATON.

MEMORIAL HOSPITAL

- 9:00-1:00. *Tumor Surgery*. Discussion. Five Year Survivals in Lymphomas and Leucemias. LLOYD F. CRAVER.
 The Use of Newer Nitrogen Mustard Compounds in the Treatment of Lymphomas and Leucemias. JOSEPH BURCHARD.
 Nitrogen Mustard As Palliative Agent in Cancer. DAVID KARNOWSKY.
 The Role of Radioactive Iodine in Thyroid Cancer. JACK TRIMBLE.

- Reasons for Delay in the Diagnosis of Cancer. JOHN E. LEACH, GUY ROBINSON.
 Preoperative and Postoperative Care for Cancer of the Lung. JOHN E. LEACH, HENRY DIAMOND.
 Study of Diagnostic Methods and Treatment of Cancer of the Lung. JOHN S. LADUE.
 The Internist's Role in Cancer. WILLIAM H. LEWIS, JR.
 Metabolic Changes in Cancer. JAMES C. ARNOLD.
 Treatment of Shock. HENRY TATUM.
 1:00-1:30. *Tumor Surgery*. Nonoperative Clinic. Follow up Results in Different Types of Breast Cancer.
 1:30-2:00. *Tumor Surgery*. Follow-up Results in Patients with Metastatic Carcinoma of the Breast with Endocrine Therapy.

METROPOLITAN HOSPITAL

- 9:00-1:00. *General Surgery*. Preoperative and Postoperative Treatment. JAMES M. WYFIELD and STAFF and LOUIS R. KAUFMAN. JOHN HERRLIN, EDWARD J. MCCABE.
 General Discussion.
 Field Balance. JOHN HERRLIN.
 Early Ambulation and Early Exercise. EDWARD J. MCCABE.
 1:00-1:20. *Obstetrics and Gynecology*.
 Interesting Ovarian Tumors. W. B. SILVERMASTER.
 Ectopic Pregnancy with Especial Reference to Posterior Culdocentesis. JOHN E. TAYLOR.
 Orthopedic and Fracture Clinic, Sixth Street Dispensary. Demonstration of End-Results of Injuries to Lower Extremities. MILTON J. WILSON and STAFF.

MONTEFIORE HOSPITAL

- 10:00-1:00. *Thoracic Surgery*. Operative and Nonoperative Clinic. ARTHUR H. ADLER, JESSE KROGH.

MOUNT SINAI HOSPITAL

- 8:30-1:00. *General Surgery*. Operative Clinic. Subtotal Gastrectomy and Infradiaphragmatic Vagotomy for Duodenal Ulcer with Stenosis. RALPH COLE.
 Presentations. Physiologic Differences between Gastric and Duodenal Ulcers. FRANK HOLLANDER.
 A Rational Approach to the Surgery of Juxta-Esophageal Ulcer. LEONARD DUCKERMAN.
 Problems in the Treatment of Gastrojejunocolic Fistula. PERRY KILGORE.
 Follow-up Results in Subtotal Gastrectomy for Gastric and Duodenal Ulcer. STOKES MACLE.
 Indications for Vagotomy in Peptic Ulcer. RALPH COLE.
 1:00-1:20. *Otolaryngology*. Operative and Nonoperative Clinic. Inflammation and Neoplastic Diseases of the Frontal Sinus.
 Carcinoma of the Larynx and Results, Treatment by Radiation Therapy. RUDOLPH KRAMER, MORRIS BROTH, ISIDORE GOLDMAN, JOSEPH DUBIN, SAMUEL ROSEN and STAFF (Surgical Amphitheatre).

NEUROLOGICAL INSTITUTE

(See Presbyterian Hospital)

NEW YORK EYE AND EAR INFIRMARY

- 10:00-1:00. *Otolaryngology*. Demonstration and Discussion. X Ray Techniques Used in Otolaryngology. IRVING SCHWARTZ.
 1:00-1:20. *Ophthalmology and Otolaryngology*. Discussion. Allergy in Eye, Ear, Nose and Throat. HOWARD WESTCOTT.

- 2:00-4:00. *Otorhinolaryngology* Demonstration Equipment Including the Biplanor Fluoroscope in the Bronchoscopic Clinic. MAXWELL D. RYAN
- 3:30-4:30. *Otorhinolaryngology* Demonstration Methods—Allergy

P.M.—*Ophthalmology* Demonstration Postoperative Treatment. MEEK and JOHNSON and ASSOCIATES.

Diagnostic Studies with Special Reference to Muscle Studies. BOYES and ASSOCIATES.

Surgery with Special Reference to Lacrimal Apparatus. PATER and McCLELLAN and ASSOCIATES.

Routine clinics of the New York Eye and Ear Infirmary will be held as usual during this period. All Fellows of the American College of Surgeons are cordially invited to attend.

NEW YORK HOSPITAL

- 9:00—*Plastic and Faciomaxillary Surgery* Operative and Nonoperative Clinic: One Stage Push Back Operation for Congenitally Short Palate.
- Results Following Treatment of Carcinoma of the Head and Neck. Case Presentations. HERBERT CONWAY
- Speech Therapy in Cases of Cleft Palate. E. FREUD.
- End-Results Following Radical Breast Amputation With Split Skin Grafting. CHARLES NEWMARK.
- Adult Tissue Extract in Wound Healing. JAMES DINGWALL.
- 9:00—*Ophthalmology* Operative Clinic. Intracapsular Cataract, Glaucoma Strabismus. JOHN McLEAM and STAFF
- 2:00—*General Surgery* Operative and Nonoperative Clinic. FRANK GLENN and STAFF
- Surgical Treatment of Acute Cholecystitis. FRANK GLENN.
- Pathology of Acute Cholecystitis. N. C. FOOTE.
- Complications of Acute Cholecystitis. S. W. MOORE.
- Diverticulitis of Large Bowel, Follow-up Studies. GARDNER CIZZO.
- Follow-up Studies of Polyps of the Large Intestine. S. W. MOORE.
- Demonstration and Exhibit. Surgical Pathological Laboratory. N. C. FOOTE.
- 2:00—*General Surgery* Demonstration Surgical Anatomy Anatomy Involved in Lumbar and Thoracolumbar Sympathectomy. ERNEST LAMPE.
- 2:00—*Otorhinolaryngology* Nonoperative Clinic. Case Presentations and Postoperative Result. Laryngofissure, Carcinoma of Antrum. Mastoiditis with Petrositis and Meningitis. Acute Frontal Sinusitis with Meningitis. ARTHUR PALMER and ASSOCIATES

NEW YORK HOSPITAL

LYING-IN HOSPITAL

- A.M.—*Gynecology* Operative Clinic: Gynecological Operations. H. J. STAMER.
- P.M.—*Obstetrics and Gynecology* Nonoperative Clinic.
- Late Results in Patients with Recurrent Abortion. CARL T. JAVERT.
- Eclampsia. H. J. STAMER.
- Treatment of Endocervicitis. RALPH W. GAUER.
- X-Ray Pelvimetry. CHARLES M. McLANE.
- Mixed Abortion. FRANK SMITH.

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL

- 9:00—*Orthopedic Surgery* Rounds. End-Result Conference. ALAN DE FOREST SMITH.
- Osteoarthritis of the Hip. FRANK STRECHFIELD.

Slipping of the Upper Femoral Epiphysis. M. B. HOWARTH.

- 1:30—*Orthopedic Surgery* General Orthopedic Clinic
- LEONIDAS A. LANTZOUNIS and STAFF
- Scoliosis Clinic. WILLIAM VON LOCKUM.

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL

- 9:00-12:00. *Tumor Surgery* Operative and Nonoperative Clinic (Amphitheatre, 6th Floor and Erdmann Auditorium) Problems in Surgery of Tumors of Breast, Head and Neck.
- 2:00-5:00. *Traumatic Surgery* Operative and Nonoperative Clinic (Amphitheatre, 6th Floor and Erdmann Auditorium)

PRESBYTERIAN HOSPITAL

- 8:00—*General Surgery* Operative Clinic: Surgery of the Pancreas. JOHN S. LOCKWOOD, WILLIAM B. PARSONS.
- Surgery of the Spleen. LOUIS M. ROUSSELOT ROBERT H. E. ELLIOTT
- Portacaval Anastomosis. ARTHUR H. BLAKEMORE.
- Resection of Maxilla For Carcinoma. MAURICE J. HICKRY
- 2:00-4:00. *General Surgery* Nonoperative Clinic: Tissue Culture as an Adjunct to Surgery. MARGARET MURRAY
- Phlebograms of the Lower Extremity. DAVID C. BULL.
- Oxidized Cellulose in Surgery. VIRGINIA R. FRANTZ.
- Transfusions and the Rh Factor. JOHN SCUMMER.
- Indications for Portacaval Shunt. ARTHUR H. BLAKEMORE.

PRESBYTERIAN HOSPITAL

BABIES HOSPITAL

- 9:00—*General Surgery* Operative Clinic. Ward Rounds. Members of Staff.
- 2:00—*General Surgery* Nonoperative Clinic.
- Congenital Diaphragmatic Hernia. Follow-up. EDWARD J. DOWMAN
- An Analysis of the Neoplasms in Childhood Encountered at Babies Hospital in the Past Ten Years. DOROTHY H. AMSTERDAM.
- Meconium Ileus. Presentation of Cases. Motion Pictures Illustrating Pathology and Operative Procedure. ROBERT B. HIATT
- Acute Appendicitis in Children. A Comparison of the Last Two Five-year Periods with and without Chemotherapy. EARL C. TAYLOR.

PRESBYTERIAN HOSPITAL

NEUROLOGICAL INSTITUTE

- 9:00-12:00. *Neurosurgery* Operative Clinic: Cases Previously Shown Clinically at the Tuesday Morning Staff Conference.

PRESBYTERIAN HOSPITAL

SLOANE HOSPITAL FOR WOMEN

- 9:00—*Obstetrics and Gynecology* Operative Clinic.
- Total Hysterectomy. E. COLLIER.
- 10:30—*Obstetrics and Gynecology* Operative Clinic.
- Myomectomy. HOWARD C. TAYLOR, JR.
- 2:00—*Obstetrics and Gynecology* Radiology: Implantation of Radium for Carcinoma of the Cervix. JAMES CORSCADEN, S. GORRIGLO.
- 3:00—*Obstetrics and Gynecology* Nonoperative Clinic: Late Follow-up Results in Carcinoma of the Cervix. JAMES CORSCADEN

PRESBYTERIAN-NEW YORK ORTHOPEDIC HOSPITALS

Fracture Service

9:00-1:00. *Fractures and Traumatic Surgery* Operative Clinic.

1:30-4:00. *Fractures and Traumatic Surgery* Nonoperative Clinic. Complicated Elbow Fractures with Follow-up Results. **FREDERICK M. SMITH.**

Replacement of Articular Elements. **STEWART S. HUNACK.**

ROOSEVELT HOSPITAL

9:00- *Gynecology* Operative Clinic. **THOMAS C. PIERCE**, **ARTHUR V. GREGG** and **STAFF**

1:00- *Gynecology* Nonoperative Clinic. The Early Results of Malignancies of the Female Pelvic Organs. Prostate of the Uterus, etc.

3:00- *Gynecology* Operative Clinic. Suprapubic Prostatectomy. **SIMON A. BEISLER** and **STAFF**
Nonoperative Clinic. The Presentation of Patients, Illustrating the Results of Urological Procedures. T. tal Cystectomy With Skin and Sigmoidal Implantation. The Reimplantation of Skin Uterostomies Into the Bowel.

ST LUKE'S HOSPITAL

8:30-1:00. *General Surgery* Operative Clinic. **WILLIAM MACFAR** and **STAFF**

1:00-1:30. *General Surgery* Clinical Demonstrations. Benign Intrathoracic Tumors. **ALEXANDER ADA.**
Follow-up Results of Surgery of Gall Bladder and Bile Ducts. Ten-year Study. **EDWARD DOKOVAN.**
Trends in Cesarean—Technique Anesthesia. **EDWARD BURFORD** and **STAFF**

Management of Hemorrhage for Gastric and Duodenal Ulcers. **ROBERT FRANK.**

1:00-4:00. *Ophthalmology* Operative Clinic. **GUTHRIE FRY** and **STAFF**

4:00-5:00. *Ophthalmology* Clinical Demonstrations. Glaucoma. Results of Operation. **GUTHRIE FRY.**
Extracocular Muscle Surgery. Follow-up Results. **HENRY SMITH.**

ST VINCENT'S HOSPITAL

9:00- *Gynecology and Obstetrics* Operative Clinic. Vaginal Plasticity. Abdominal Hysterectomy. Vaginal Hysterectomy. Cesarean Section. **JOHN McGRATH**, **JAMES P. HENKERT**, **THOMAS E. LAVELL**, **JOSPH E. COLE**, **THOMAS IOWING**, **ROBERT LOWELL**, **JOHN KILGOUR**, **WALTER P. GAGE**

1:00- *General Surgery* Round Table Conference. Use of Transverse Incisions. **JOHN A. LAWLER.**
Malignant Tumors Small Intestine. **CLARENCE P. HOWLEY.**

3:00- *Radiology* Roentgen Diagnosis of Lesions of Small Intestine. Differential Diagnosis of Mechanical and Adynamic Ileus. **WALLACE MAYER** and **ASSOCIATES.**

5:00- *Gynecology and Obstetrics* Round Table Conference. Study of Vaginal Spread for Carcinoma of Cervix. Differential Diagnosis in Cases of Acute Pelvic Pathology. Indications for Cesarean Section. Choice of Operation in Uterine Prolapse. **McGRATH** and **ASSOCIATES.**

5:30- *Pathology* Nonoperative Clinic. Study of Abdominal and Chest Fluids for Evidence of Malignancy. Display of First Pathological Material. Display and

Demonstration of System Diseases by Kodachrome Slides. **A. ROTTINO** and **ASSOCIATES.**

3:00- *General Surgery* Thrombosis and Embolism. **LOUIS F. SANDMAN.**

SLOANE HOSPITAL FOR WOMEN

(See Presbyterian Hospital)

VETERANS ADMINISTRATION HOSPITAL

9:00- *General Surgery* Operative Clinic. **EDWIN SELF**, **DAVID I. PINDER.**

9:00- *Neurosurgery* Operative Clinic. Prefrontal Lobotomy. **JOHN E. SCARFF**, **EDWIN KRIEGER.**

9:00- *Genitourinary Surgery* Operative Clinic. **LOUIS SPRIVACK**, **EDWIN J. DREW.**

9:00- *Plastic Surgery* Operative Clinic. **HENRIET CONWAY**, **CORNELIUS J. KRAMER.**

9:00- *Orthopedic Surgery* Conference. Presentation of End Results—Bon Tumors Bone and Joint Tuberculosis. Presentation of Cases. **PHILIP D. WILSON**, **SYDNEY N. EICHENSOHLT**, **ROBERT PATTERSON**, **FRANK E. STONCHFIELD**, and **RESIDENT STAFF.**

9:30-11:30. *Medical Rehabilitation Clinic.* **HARRY KESLER**, **KARL HARTFELDER**, **LEWIS D. STEIN**, **BERNARD STOLL**, **JACOB BYER.**

1:00- *General Surgery* Nonoperative Clinic. Result of Vagus Resection. **P. K. SUTHER**, **JOHN ECKEL**, **CHARLTON HOLMAN**, **FRANK J. MCGOWAN**, **CHARLES PRIVILEY**, and **RESIDENT STAFF.**

4:00- *Neurosurgery* Nonoperative Clinic. Prefrontal Lobotomy. **JOHN E. SCARFF**, **THOMAS RICKER**, **HELAND L. FLOWERS.**

5:00- *Neurosurgery* Conference. Complications in Frontal Cranioplasties Involving Frontal Sinus. Surgery of the Sympathetic Nervous System for Painful Conditions. Leptomeningeal and Porencephalic Cyst with Increased Intracranial Pressure. Surgical Treatment of Phantom Limb. Compression of the Anterior Pyramidal Tract by Cervical Midline Disc. Lucic Pachymeningitis with Increased Intracranial Pressure. **JOHN E. SCARFF**, **Fritz CHASER**, **E. G. KRIEGER**, **J. LAWRENCE POOL.**

5:30- *Urology* Conference. **ANDREW DEAN**, **LOUIS SPRIVACK**, **FREDERICK SPRIVACK**, **EDWIN J. DREW**, **WILLIAM WHITEHOUSE**, **JOHN K. LATTIMER**, and **RESIDENT STAFF.**

EXHIBITS

Anesthesia Section	Results of Vagus Resection
Bronchogenic Carcinoma	Pathology Section
Review of 600 Cases	Medical Illustrations
Intracranial Neoplasms	Laboratory
Residency Training Program	Plastic Surgery
Organization of Surgical Division	Prosthetic Appliances

WOMAN'S HOSPITAL

8:30- 3:00. *Obstetrics and Gynecology* Treatment of Neoplasms of the Female Genital Tract. Management of Birth Injuries and Uterine Displacements. Diagnosis and Treatment of Obstetric Complications. End-Results of Treatment. These Conditions Will Be Discussed.

During the course of the morning the routine for training of Residents in Gynecology and Obstetrics will be outlined.

The pathologist will give demonstrations of obstetric and gynecologic pathological specimens.

CLINICS IN BROOKLYN—LONG ISLAND HOSPITALS

Thursday

BROOKLYN EYE AND EAR HOSPITAL

- P.M. *Ophthalmology Otolaryngology and Facial Surgery* Late Results in Focomaxillary Surgery Late Results in Laryngectomies. Late Results in Glaucoma Surgery Angioscotometry Exhibit. Motion Picture Demonstration on the Development of the Human Eye as Shown by Animation.
- P.M. *Plastic Surgery* Operative Clinic Nasal.

CUMBERLAND HOSPITAL

- 9:00-12:00. *Fractures and Traumatic Surgery* Pinning for Femur Neck Fracture. LEO FARKE and STAFF
Late Results in Fracture of Femur Neck.
Traumatic Abdomen. JOSEPH I. ANTOV
Ward Rounds with X ray Studies of Various Types of Fractures.
- 1:00-5:00. *Fractures and Traumatic Surgery* Nonunion Late Results and General Discussion JOSEPH NEVINS and STAFF
Ward Rounds with Demonstration of Apparatus in Use. Gadgets and Their Use in Fracture Treatment.
Head Injuries. Late Results. FRANK TURNER

HOUSE OF ST GILES THE CRIPPLE

- 11:00- *Orthopedic Surgery* Abduction Traction Splint for Congenital Dislocation of Hip.
Shoulder Fusion, for Polio Flail Shoulders five year Follow-up. Demonstration of Cases.
Follow up on Shelf Operation for Congenital Dislocation of Hip Presentation of Cases. Recurrent Clubfoot. Demonstration of Cases Following Resection of Head of Talus Plus Transplantation of Anterior Tibial Tendon.
Demonstration of Cases Following Teres Major Transplantation for Obstetrical Palsy

JEWISH HOSPITAL

- 8:00-10:00. *General Surgery* Operative Clinic. PAUL W. ASCHNER and STAFF
General Surgery Operative Clinic. LEO S. SCHWARTZ and STAFF
- 10:00-12:00. *Gynecology and Obstetrics* Nonoperative Clinic.
Intrapelvic Hematomas of Vulva. PAUL PEDOWITZ.
Subcutaneous Heparin in Thromboembolic Disease in Gynecology and Obstetrics. HARRY J. GREENE.
A Study of Pelvic Drive in Obstetrics. EDWIN M. GOLD.
Hyaluronidase and Infertility. CHARLES BIRKENBO.
Failed Forceps. ISADORE DATCHMAN WILLIAM FOMERANCE.
Studies with Gonadogen. SAMUEL A. WOLFE, IRWIN NICHOLS.
- 10:00-12:00. *Gynecology and Obstetrics* Nonoperative Clinic
Diagnosis and Treatment of Solitary Cyst of the Kidney by Aspiration and Injection. ABRAHAM D. SEGAL.
Treatment of Hydrocele by Sclerosing Agents. LOUIS H. BARETZ.
Periostitis and Ostitis Pubis Complicating Urologic Procedures. ZACHARY R. COTTLER SAMUEL PARMAS.
Obstructive Uropathy in Children. PERRY KATZEN.
Serum Acid Phosphatase in the Diagnosis and Management of Carcinoma of the Prostate. ISADORE KIMMEL, PAUL W. ASCHNER.

KINGS COUNTY HOSPITAL

- 8:30- *General Surgery* (Long Island College Surgical Service)
Operative Clinics
Gastric Resection. EDWARD P. DUNN
Large Bowel Resection. CHARLES B. JONES.
For Gall-Bladder Disease. PHILIP E. LEAR.
Ligation of Patent Ductus Arteriosus. JOHN L. MADDEN
- 8:30- *Neurosurgery* Operative Clinic JEFFERSON BROWDER and STAFF
Dorsal Cordotomy for Painful Phantom Foot. E. JEFFERSON BROWDER.
Sympathectomy for Arterial Hypertension. EVERETT CORRADINI.
Capsular Fiber Section for Parkinsonism. E. JEFFERSON BROWDER.
Dorsal Rhizotomy for Spasticity of Cerebral Palsy. FRANK TURNER
- 9:00- *General Surgery* Operative Clinic JOSEPH TENOPPE and STAFF Subject to be Announced
- 9:00- *Thoracic Surgery* Operative Clinic
Segmental Resection of the Lung. LEW A. HOCHBERG

KINGS COUNTY HOSPITAL

LONG ISLAND COLLEGE DIVISION

- 8:30- *General Surgery* Operative Clinics (Operating Pavilion—"B" Building)
Gastric Resection. EDWARD P. DUNN
Large Bowel Resection. CHARLES B. JONES.
Gall Bladder and Common Duct Exploration. PHILIP E. LEAR.
Ligation Patent Ductus Arteriosus. JOHN L. MADDEN
- 1:45- *General Surgery* Nonoperative Clinics (Nurses Amphitheatre)
Diagnosis and Treatment of Lymphogranuloma Venereum, Anus, Rectum, and Colon. CHARLES B. JONES.
Paraduodenal Hernia, Report of Four Cases. PHILIP E. LEAR.
Cosmetic Incision for Excision of Benign Breast Tumors and for Supportive Diseases of the Female Breast. GARTANOT DE YOAKKA.
Tetanus—A Surgical Problem. Experience with Five Hundred Cases in China. PHILLIPS F. GREENE.
Gastrojejunocolic Fistula, Six Case Reports. JOHN L. MADDEN
Follow-up Results in Hip Nailing Operations in Femoral Neck. ARNOLD F. SAMMIS.
- 1:00- *General Surgery* Nonoperative Clinic
Subjects to be Announced.
- 2:00- *General Surgery* Nonoperative Clinic
Diagnosis and Treatment of Lymphogranuloma Venereum of Anus, Rectum and Colon. CHARLES B. JONES.
Paraduodenal Hernia, Report of Four Cases. PHILIP E. LEAR.
Surgical Treatment of Gastrojejunocolic Fistula, Report of Six Cases. JOHN L. MADDEN
Cosmetic Incision for Excision of Benign Tumors of the Breast and for Supportive Mastitis. GARTANOT DE YOAKKA.
End Results in Hip Nailing for Fracture of the Femoral Neck. ARNOLD F. SAMMIS.
Tetanus as a Surgical Problem. PHILLIPS F. GREENE.

PRESBYTERIAN NEW YORK ORTHOPEDIC HOSPITALS

Fracture Service

9:00-12:00. *Fractures and Traumatic Surgery* Operative Clinic.

30-4:00. *Fractures and Traumatic Surgery* Nonoperative Clinic. Complicated Elbow Fractures with Follow-up Results. FREDERICK M. SMITH.
Replacement of Articular Elements. STEPHAN S. HUCKLE.

ROOSEVELT HOSPITAL

9:00-12:00. *Gynecology* Operative Clinic. THOMAS C. PIERCE, ARTHUR V. GIBBLEY and STAFF

12:00-1:00. *Gynecology* Nonoperative Clinic. The Early Results of Malignancies of the Female Pelvic Organs, Prostate of the Uterus, etc.

1:00-2:00. *Gynecology* Operative Clinic. Sepsis, Prostatectomy. SIMON A. BEISLER and STAFF
Nonoperative Clinic. The Presentation of Patients, Illustrating the Results of Urological Procedures. Total Cystectomy With Skin and Sigmoidal Implantation. The Replantation of Skin Ureterostomies Into the Bowel.

ST LUKE'S HOSPITAL

8:30-12:00. *General Surgery* Operative Clinic. WILLIAM MACFARLANE and STAFF

12:00-1:00. *General Surgery* Clinical Demonstrations. Benign Intrathoracic Tumors. ALEXANDER ADAMS. Follow-up Results of Surgery of Gall Bladder and Bile Ducts. Ten Year Study. EDWARD DOROVAN. Trends in Care—Technique. Anesthetics. EDWARD BURDETTE and STAFF

1:00-2:00. *Management of Hemorrhage for Gastric and Duodenal Ulcers*. ROBERT FRANKEL

2:00-4:00. *Ophthalmology* Operative Clinic. GUTENBERG FREY and STAFF

4:00-5:00. *Ophthalmology* Clinical Demonstrations. Glaucoma. Results of Operation. GUTENBERG FREY
Extraocular Muscle Surgery. Follow-up Results. HENRY SHAPIRO.

ST VINCENT'S HOSPITAL

9:00-12:00. *Gynecology and Obstetrics* Operative Clinic. Vaginal Plasticity. Abdominal Hysterectomy. Vaginal Hysterectomy. Cesarean Section. JOHN McGRATH, JAMES P. HICKOK, THOMAS E. LAYELL, JOSEPH E. COHR, THOMAS JOYCE, ROBERT LOWRIE, JOHN KILGUS, WALTER P. GAGE.

12:00-1:00. *General Surgery* Round Table Conference. Use of Transverse Incisions. JOHN A. LAWLER.
Malignant Tumors Small Intestine. CLAUDE P. HOWLEY.

1:00-2:00. *Radiology* Roentgen Diagnosis of Lesions of Small Intestines. Differential Diagnosis of Mechanical and Adynamic Ileus. WALLACE MAYER and ASSOCIATES.

2:00-3:00. *Gynecology and Obstetrics*. Round Table Conference.

Study of Vaginal Spread for Carcinoma of Cervix. Differential Diagnosis in Cases of Acute Pelvic Pathology. Indications for Cesarean Section. Choice of Operation in Uterine Prolapse. McGRATH and ASSOCIATES.

3:00-4:00. *Pathology* Nonoperative Clinic. Study of Abdominal and Chest Fluids for Evidence of Malignancy. Display of First Pathological Material. Display and

Demonstration of System Diseases by Kodachrome Slides. A. ROTTINO and ASSOCIATES.

3:00-4:00. *General Surgery* Thrombosis and Embolism. LOUIS F. SANDMAN

SLOANE HOSPITAL FOR WOMEN

(See Presbyterian Hospital)

VETERANS ADMINISTRATION HOSPITAL

9:00-12:00. *General Surgery* Operative Clinic. EDWIN SELF, DAVID K. PIERCE.

12:00-1:00. *Neurosurgery* Operative Clinic. Prefrontal Lobotomy. JOHN E. SCARFF, ERICH KREIBER.

1:00-2:00. *General Surgery* Operative Clinic. LOUIS SEYACK, EDWIN J. DREW.

2:00-3:00. *Plastic Surgery* Operative Clinic. HERBERT CONWAY, CORNELIUS J. KRAMEL.

3:00-4:00. *Orthopedic Surgery* Conference. Presentation of End-Results—Bone Tumors, Bone and Joint Tuberculosis. Presentation of Cases. PHILIP D. WILSON, SYDNEY N. ENCHENBOWER, ROBERT PATTERSON, FRANK E. STORCHFIELD, and RESIDENT STAFF

4:00-5:00. *Medical Rehabilitation* Clinic. HARRY KESLER, KARL HANFORD, IRWIN D. STEIN, BENJAMIN STOLL, JACOB BEER.

5:00-6:00. *General Surgery* Nonoperative Clinic. R. Velt of Vagus Resection. P. K. SAUER, JOHN ECKEL, CHRISTOPHER HOLMAN, FRANK J. MCGOWAN, CHARLES PRIVITERA, and RESIDENT STAFF

6:00-7:00. *Neurosurgery* Nonoperative Clinic. Prefrontal Lobotomy. JOHN E. SCARFF, THOMAS RAY, HILARIO L. FLOWERS.

7:00-8:00. *Neurosurgery* Conference. Complications in Frontal Cranioplasty Involving Frontal Sinus. Surgery of the Sympathetic Nervous System for Painless Conditions. Leptomenigeal and Porencephalic Cyst with Increased Intracranial Pressure. Surgical Treatment of Phantom Limb. Compression of the Anterior Pyramidal Tract by Cervical Midline Disc. Latent Pachymeningitis with Increased Intracranial Pressure. JOHN E. SCARFF, FRANK CHAMBER, E. G. KREIBER, J. LAWRENCE POOL.

8:00-9:00. *Urology* Conference. ARCHIE DEAN, LOUIS SEYACK, PETER SEYLER, EDWIN J. DREW, WILLIAM WRIGHT, JOHN K. LATTIMER, and RESIDENT STAFF

EXHIBITS

Anesthesia Section	Results of Vagus Resection
Bronchogenic Carcinoma	P. thology Section
Review of two Cases	Medical Illustrations
Intracranial Neoplasms	Laboratory
Residency Training Program	Plastic Surgery
Organization of Surgical Division	Prosthetic Appliances

WOJAN'S HOSPITAL

8:30-10:00. *Obstetrics and Gynecology* Treatment of Neoplasms of the Female Genital Tract. Management of Birth Injuries and Uterine Displacements. Diagnosis and Treatment of Obstetric Complications. End-Results of Treatment of These Conditions Will Be Discussed.

During the course of the morning the routine for training of Residents in Gynecology and Obstetrics will be outlined.

The pathologist will give demonstrations of obstetric and gynecologic pathological specimens.

CLINICS IN BROOKLYN—LONG ISLAND HOSPITALS

Thursday

BROOKLYN EYE AND EAR HOSPITAL

- P.M. *Ophthalmology, Otolaryngology and Faciomaxillary Surgery* Late Results in Faciomaxillary Surgery Late Results in Laryngectomies. Late Results in Glaucoma Surgery Angioscotomy Exhibit. Motion Picture Demonstration on the Development of the Human Eye as Shown by Animation
- P.M. *Plastic Surgery* Operative Clinic Nasal

CUMBERLAND HOSPITAL

- 9:00-12:00. *Fractures and Traumatic Surgery* Pinning for Femur Neck Fracture. LEO FASKE and STAFF
Late Results in Fracture of Femur Neck.
Traumatic Abdomen JOSEPH I. AUSTON
Ward Rounds with X ray Studies of Various Types of Fractures.
- 2:00-5:00. *Fractures and Traumatic Surgery* Nonunion Late Results and General Discussion JOSEPH NEVINS and STAFF
Ward Rounds with Demonstration of Apparatus in Use. Gadgets and Their Use in Fracture Treatment.
Head Injuries. Late Results. FRANK TURNEY

HOUSE OF ST GILES THE CRIPPLE

- 11:00- *Orthopedic Surgery* Abduction Traction Splint for Congenital Dislocation of Hip.
Shoulder Fusion for Polio Flail Shoulders five-year Follow-up Demonstration of Cases
Follow-up on Shell Operation, for Congenital Dislocation of Hip Presentation of Cases. Recurrent Clubfoot, Demonstration of Cases Following Resection of Head of Talus Plus Transplantation of Anterior Tibial Tendon.
Demonstration of Cases Following Teres Major Transplantation for Obstetrical Palsy

JEWISH HOSPITAL

- 8:00-10:00. *General Surgery* Operative Clinic. PAUL W. ASCHNER and STAFF
General Surgery Operative Clinic. LEO S. SCHWARTZ and STAFF
- 10:00-12:00. *Gynecology and Obstetrics* Nonoperative Clinic
Puerperal Hematomas of Vulva. PAUL PEDOWITZ
Subcutaneous Heparin in Thromboembolic Disease in Gynecology and Obstetrics. HARRY J. GREENE
A Study of Pelvic Drive in Obstetrics. EDWIN M. GOLD
Hyaluronidase and Infertility CHARLES BRONKHOFF
"Failed Forceps." ISADORE DAKSHMAN WILLIAM POWERS
Studies with Gonadogen. SAMUEL A. WOLFE, IRWIN NERZIS
- 10:00-12:00. *Gynecology and Obstetrics* Nonoperative Clinic
Diagnosis and Treatment of Solitary Cyst of the Kidney by Aspiration and Injection. ABRAHAM D. SZOAL
Treatment of Hydrocele by Sclerosing Agents. LOUIS H. BARTZ
Peritonitis and Otitis Pubis Complicating Urologic Procedures. ZACHARY R. COTTLER, SAMUEL PARKMAN
Obstructive Uropathy in Children. PERRY KATZKY
Serum Acid Phosphatase in the Diagnosis and Management of Carcinoma of the Prostate ISADORE KIMMEL, PAUL W. ASCHNER

KINGS COUNTY HOSPITAL

- 8:30- *General Surgery* (Long Island College Surgical Service)
Operative Clinics
Gastric Resection. EDWARD P. DUNN
Large Bowel Resection. CHARLES B. JONES
For Gall Bladder Disease. PHILIP E. LEAR.
Ligation of Patent Ductus Arteriosus JOHN L. MADDEN
- 8:30- *Neurosurgery* Operative Clinic JEFFERSON BROWDER and STAFF
Dorsal Cordotomy for Painful Phantom Foot. E. JEFFERSON BROWDER
Sympathectomy for Arterial Hypertension EVERETT CORRADINI
Capsular Fiber Section for Parkinsonism. E. JEFFERSON BROWDER
Dorsal Rhizotomy for Spasticity of Cerebral Palsy FRANK TURNEY
- 9:00- *General Surgery* Operative Clinic. JOSEPH TENORIS and STAFF Subject to be Announced.
- 9:00- *Thoracic Surgery* Operative Clinic
Segmental Resection of the Lung LEW A. HOCHBERG

KINGS COUNTY HOSPITAL

LONG ISLAND COLLEGE DIVISION

- 8:30- *General Surgery* Operative Clinics (Operating Pavilion—"B" Building)
Gastric Resection. EDWARD P. DUNN
Large Bowel Resection CHARLES B. JONES
Gall Bladder and Common Duct Exploration. PHILIP E. LEAR
Ligation Patent Ductus Arteriosus. JOHN L. MADDEN
- 1:45- *General Surgery* Nonoperative Clinics (Nurses Amphitheatre)
Diagnosis and Treatment of Lymphogranuloma Venereum, Anus, Rectum, and Colon CHARLES B. JONES
Paraduodenal Hernia, Report of Four Cases. PHILIP E. LEAR
Cosmetic Incision for Excision of Benign Breast Tumors and for Suppurative Diseases of the Female Breast. GAUTAMU DE YOAKHA
Tetanus—A Surgical Problem. Experience with Five Hundred Cases in China. PHILLIPS F. GREENE
Gastrojejunocolic Fistula, Six Case Reports JOHN L. MADDEN
Follow-up Results in Hip Nailing Operations in Femoral Neck. ARNOLD F. SAMMIE
- 1:00- *General Surgery* Nonoperative Clinic
Subjects to be Announced.
- 1:00- *General Surgery* Nonoperative Clinic.
Diagnosis and Treatment of Lymphogranuloma Venereum of Anus, Rectum and Colon CHARLES B. JONES
Paraduodenal Hernia, Report of Four Cases. PHILIP E. LEAR
Surgical Treatment of Gastrojejunocolic Fistula, Report of Six Cases. JOHN L. MADDEN
Cosmetic Incision for Excision of Benign Tumors of the Breast and for Suppurative Mastitis GAUTAMU DE YOAKHA
End Results in Hip Nailing for Fracture of the Femoral Neck. ARNOLD F. SAMMIE
Tetanus as a Surgical Problem. PHILLIPS F. GREENE

- 800- *Neurosurgery* Nonoperative Clinic:
The Cerebellar Hemangioblastomas. EVERETT COE
RADFORD.
Cysticercosis Disease of the Brain. LESTER REED.
Surgery for Parkinson's Disease. E. JEFFERSON BROWDER.
Management of Fractures of the Spine with Spinal Cord
Damage. FRANK TURKEY.
Subdural Hematoma. RICHARD GRIGGS.
8200- *Thoracic Surgery* Nonoperative Clinic.
Lung Abscess As Seen at the Kings County Hospital.
ALFRED D. BUCHANAN.
Pneumothorax in Cases of Pulmonary Tuberculosis.
EDWIN H. GRIFFIN.
Some Experiences in the Management of Chronic Em-
physema. ELTON K. JOHNSON.
Paradoxical Respiration—Its Causes, Consequences and
Treatment. LEW A. HOCKENRUD.

LONG ISLAND COLLEGE HOSPITAL

- 700- *Obstetrics and Gynecology* Operative and Non-
operative Clinics, and Demonstrations. Members of
the staff.
The Departments of Ophthalmology and Otolaryngology
will conduct their programs at the Brooklyn Eye and
Ear Hospital.

CLINICS IN NEW YORK HOSPITALS

Friday

- BELLEVUE HOSPITAL—FIRST (COLUMBIA
UNIVERSITY) SURGICAL DIVISION
8:00-12:00. *Thoracic Surgery* Operative Clinic (C & D
Building, 5th Floor Operating Room): FRANK B
BERRY and STAFF
BELLEVUE HOSPITAL—THIRD (NEW YORK
UNIVERSITY) SURGICAL DIVISION
8:00-12:00. *Anesthesia*. Demonstration (C & D Operating
Rooms, 5th Floor C & D Building) Anesthesia in
Thoracic Surgery. E. A. ROVENSTOCK and STAFF.
A.M. *Radiology*. Demonstrations (I & K Building,
Ground Floor). IRA L. KAPLAN and STAFF.
Radiation Therapy as an Adjunct Method of Treatment
in Genitourinary Neoplasm. Alternate.
BELLEVUE HOSPITAL—FOURTH (NEW YORK
UNIVERSITY) SURGICAL DIVISION
8:00-9:30. *General Surgery and Fractures*. Operative
Clinics. (Operating Rooms K-5 & K-6) ARTHUR
McQUILLAN and STAFF.
Thyroid Surgery. ARTHUR S. McQUILLAN (Operating
Room A).
Stomach Surgery. J. WILLIAM HINTON (Operating
Room B).
Intestinal Surgery. LESTER BATHURSTACH (Operating
Room C).
Gall-Bladder Surgery. EDWARD V. DENCKEN (Operat-
ing Room D).
Smith-Petersen Nailing for Fracture of Neck of Femur.
KROGH M. LEVIN (Bone Room K-6).
9:00-12:00. *General Surgery and Fractures*. Nonoperative
Clinics (I & K Building, Stewart Amphitheatre,
Ground Floor) End Results. ARTHUR S. McQUILLAN
and STAFF.
Thyroids. ARTHUR S. McQUILLAN.
Peptic Ulcers. J. WILLIAM HINTON.

METHODIST HOSPITAL

- 9:00-12:00. *Obstetrics and Gynecology* Operative Clinics
(Buckley Building—8th Floor).
Vaginal Hysterectomy. Total Hysterectomy. (Other
Operative Procedures to be Scheduled Later). G. H.
DAVIS and STAFF.
9:00-12:00. *Obstetrics and Gynecology* Demonstrations
(Maternity Building—Main Floor).
Ball Technique in X-Ray Menstruation of Pelvis. BETT
LEE GOVARD.
Cord Transfusion. B. MYER.
Inspection of Clinics, Wards and Delivery Rooms.
RESIDENT STAFF.
Maternal Mortality and Morbidity in Obstetrics. SER-
MAN.
100- *Obstetrics and Gynecology* Nonoperative Clinic.
G. H. DAVIS, Chairman.
Fibroids and Ovarian Tumors in Pregnancy. SAMPSON.
Fetal Mortality in Prolonged Labor. GAYSON.
Leiomyosarcoma. Contract with Cellular Myofibroscyo-
mas. FRANK HOWE.
Ablatio Placentae. BELL.
Manual Removal of Placenta. H. MYER.
Anesthesia in Cesarean Section. H. ACHES, JR.
Wedge Resection of Ovary for Polycystic Disease. S. C.
HALL.

- Fracture of the Neck of the Femur. KROGH M. LEVIN.
Stricture of Rectum Due to Lymphogranuloma Ven-
ereum. LESTER BATHURSTACH.
Gall-Bladder Disease. EDWARD V. DENCKEN.

BETH ISRAEL HOSPITAL

- 9:00-12:00. *Orthopedic Surgery*. BALKENWED and STAFF.
12:00-5:00. *Obstetrics*. LARGACK, SCARDIN.

FLOWER AND FIFTH AVENUE HOSPITALS

- 9:00-12:00. Water Balance, etc. FRANCIS D. SPIER, JOHN
HEERLEIN.
Lyophilized Amino Acids. MICHAEL G. MULLER.
Relationship of Amino Acid Composition of Foods.
R. J. BLOCK, H. H. MITCHELL.
100-12:00. The Prevention of Renal Complications by
Therapy with Mixtures of Sulfonamides—or—Phthal-
ylsulfacetamide in Surgery of Colon. DAVID LEHR.
100-3:00. Presentation of Plans for Resident Training in
Surgery. JAMES M. WHITFIELD.

HARLEM HOSPITAL

- 9:00-12:00. Abdominal Catastrophes—Operative and
Nonoperative Clinic and Ward Rounds. B. N. BASS,
A. A. ZIMMERMAN, J. L. WILSON, A. DEL. MATHEW.
12:00-5:00. Clinico-Pathological Conference. L. T.
WRIGHT, S. WEINTRAUB and STAFF.

HOSPITAL FOR JOINT DISEASES

- 9:00-12:00. *General Surgery* Operative Clinic. Carcinoma
of Colon. Carcinoma of Rectum. Nonoperative Clinic.
Intra-Abdominal Rersection with Anastomosis for Car-
cinoma of the Rectum. A. J. BELLER.
100-12:00. *Neurosurgery* Operative Clinic. Operations of
Brain and Spinal Cord. ABRAHAM KAPLAN.

HOSPITAL FOR SPECIAL SURGERY

- 8:30-12:00. *Orthopedic Surgery*. Adult Service.

- 2:00-5:00. *Orthopedic Surgery* Operative and Nonoperative Clinic
 Osteoid Osteoma. MILTON HELPERN RAYMOND LEWIS
 Bone Grafts without Internal Fixation. PETER RIZZO
 Bridging of Defects of Long Bones of the Extremities
 JOHN FLAMAGAN
 The Bone Bank. PHILIP D. WILSON
 Spine Fusion with Internal Fixation. L. RAMSAY
 STRAUSS
 Problems in the Treatment of Scoliosis. JOHN R. COSSA

LYING-IN HOSPITAL
 (See New York Hospital)

MANHATTAN EYE, EAR AND THROAT
 HOSPITAL

- 9:30- *Otolaryngology* Demonstration Audiometry
 Selection and Fitting of Hearing Aids Retraining
 Residual Hearing. WERTHEIMER, NEUMARKER.
 10:00- *Ophthalmology* Demonstration Corneal
 Grafting Technique on Rabbits. H. M. KATZM
 10:00- *Neurosurgery* Operative Clinic. Facial
 Nerve Graft
 Operation and Demonstration of Postoperative Results.
 T. G. TICKLER.
 2:00- *Otolaryngology* Operative Clinic. Tonsil Sur-
 gery Preoperative and Postoperative Procedure. R.
 J. BELLIARD
 2:00- *Ophthalmology* Orthoptic Clinic. F. C. KEIL,
 JR., E. KRAUBER.

MEMORIAL HOSPITAL

- 9:00-10:30. *Tumor Surgery* Nonoperative Clinic. End
 Results Following Abdominoperineal Resection for
 Cancer of the Rectum Treatment of Cancer of the
 Colon Management of Squamous Cancer of the Anus
 and the Rectum.
 10:30-12:00. *Tumor Surgery* Nonoperative Clinic. End
 Results in the Treatment of Cancer of the Stomach a
 Study of Over 1000 Cases. End-Results in the Treat-
 ment of Malignant Melanomas a Study of Over 900
 Cases.
 2:00-3:00. *Thoracic Surgery* Nonoperative Clinic. Asym-
 ptomatic Thoracic Tumors End-Result in Surgically
 Treated Cases of Carcinoma of the Cervical Esopha-
 gus. End Results in Surgically Treated Cases. WAR-
 BURG.
 3:00-4:00. *Tumor Surgery* Nonoperative Clinic. End-
 Results in Treatment of Bone Tumors. COLEY
 4:00-5:00. *Tumor Surgery* Discussion Cancer in Child-
 ren Presentation of Followed Cases. DARGENT.

METROPOLITAN HOSPITAL

- 9:00-12:00. *General Surgery* Operative Clinic: Surgery of
 Stomach and Duodenum. JAMES M. WINTFIELD and
 STAFF
 Indications. EDWARD J. McCABE.
 Vagotomy JAMES M. WINTFIELD.
 Duodenal Closure and Complications. KENNETH C.
 PEACOCK.
 Surgery of Gall Bladder and Pancreas. KENNETH C.
 PEACOCK.
 Retroperitoneal Tumors. KENNETH C. PEACOCK, JOHN
 SNIDER.
 Peritoneal Spaces. JOHN HEERLIN
 1:00-4:00. *Plastic and Reconstructive Surgery* Operative
 and Nonoperative Clinic. DAVID M. MAYER, JOHN F.
 FORD.

MOUNT SINAI HOSPITAL

- 8:30-12:00. *Genitourinary Surgery* Operative Clinic
 Kidney Operation. LEO EDELMAN
 Nonoperative Clinic. Carcinoma in a Horseshoe Kid-
 ney. GORDON D. OPPENHEIMER.
 Bladder Neck Obstruction in Young Individuals. MORRIS
 SWICK.
 Peritoneal Insufflation. WILLIAM MENCHER.
 Emurelia Due to Ectopic Ureter. H. EVANS LEITER.
 2:00-5:00. *Neurosurgery* Nonoperative Clinic.
 Long Time Follow up in Some Neurosurgical Cases
 Case Presentations. ABRAHAM KAPLAN
 Correlation of X Ray Findings and Clinical Picture. B.
 SCHLESINGER.
 Dumbbell Tumor of the Spine. IRA COHEN
 Cranioplasty Motion Picture Demonstration S. GROSS.

NEUROLOGICAL INSTITUTE
 (See Presbyterian Hospital)

NEW YORK EYE AND EAR INFIRMARY

- 10:00-12:00. *Otolaryngology* Demonstration Anatomical
 Specimens. E. BURCHILL.
 2:00-4:00. *Otolaryngology* Discussion of Pathology with
 Lantern Slides. D. S. D. JESSUP
 The routine clinics of the New York Eye & Ear Infirmary
 will be held as usual during this period, all Fellows of
 the American College of Surgeons are cordially invited to
 attend.

NEW YORK HOSPITAL

- 9:00- *Orthopedic Surgery* Operative Clinic. FRED-
 ERICK LEE LIEBOWITZ
 2:00- *Orthopedic Surgery* Nonoperative Clinic.
 FREDERICK LEE LIEBOWITZ and ASSOCIATES.
 Volkmann's Paralysis Prevented by Sympathetic Block.
 ARTHUR CONWELL.
 Reconstruction Surgery of the Hand (Lantern Slides)
 FREDERICK L. LIEBOWITZ
 Massive Onlay Bone Grafts for Ununited Fractures
 PRESTON WADE.
 Conservative Treatment of Table Fractures of the
 Tibia. BERNARD MAIBEL.
 End Results in Treatment of Fractures of the Neck of
 the Femur by Moore Nails. NELSON CONWELL.
 2:00- *Otorhinolaryngology* Operative Clinic. Surgery
 of the Oropharynx and Nasopharynx. THOMAS GAR-
 RICK.
 3:00- *General Surgery* FRANK GLENN and STAFF
 The Chemistry of Penicillin and Streptomycin. VINCENT
 DU VIGNEAUD.
 Toxicity of Streptomycin. WALTER McDERMOTT
 Treatment of Pulmonary Tuberculosis by Streptomycin
 CARL MURCHENCKO.
 Use of Streptomycin in Treating Surgical Pulmonary
 Tuberculosis. CRANSTON HOLMAN
 Adult Tissue Extract in Wound Healing. JAMES DINO
 WALL.

NEW YORK HOSPITAL
 LYING-IN HOSPITAL

- 11:00- Obstetrical and Gynecological Staff Rounds
 A.B. - *Obstetrics and Gynecology* Operative Clinic
 Gynecological Operations by Resident Staff
 PM- *Obstetrics and Gynecology* Operative and Non-
 operative Clinic
 Cryptomenorrhea—Congenital and Acquired. THOMAS
 L. BALL.
 Results of an Operation for Urinary Incontinence.
 ANDREW A. MARCHETTI, VICTOR MARSHALL.

Pregnancy Following Outlet Operation. WILLIAM FROD
Studies on Patients with Hydranmiotic During the Past
Fifteen Years. PAUL E. MUELLER.

End-Results of the Treatment of Carcinoma of the En-
dometrium. ANDREW A. MARCHETTI, JOHN E. McAL-
LESTER.

Radiological Survey of Breaches. EL L. WILCOX.

NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL

8:00- Orthopedic Surgery Operative Clinic. ALAN
DE FOREST SMITH and STAFF

1:30- Orthopedic Surgery General Orthopedic Clinic
HALFORD HALLOCK and STAFF

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL

9:00- 30. Neurosurgery Operative Clinic (Amphi-
theatre, 6th Floor) Surgery in Hypertension

0:30- 1:00. Neurosurgery Operative Clinic Diseases of
the Vascular System.

1:00-5:00. General Surgery Operative Clinic (Amphi-
theatre 6th Floor)

PRESBYTERIAN HOSPITAL

8:00- General Surgery Operative Clinic Surgery of
The Large Bowel. DAVID C. BULL, ROBERT S. GRIN-
WELL, LOUIS M. ROCHMELLOT, HENRY S. COOPER.

Sympathectomy to Hypertension. RICHMOND I.
MOORE.

Vagotomy for Marginal Ulcer. ROBERT H. RYAN.
Wiring of Arteriosclerotic Abdominal Aneurysm. AR-
THUR H. BLANKENHORN.

1:00-4:00. General Surgery Nonoperative Clinic Physio-
logy of Peritonitis. JOHN S. LOCKWOOD.

Prevention of Wound Infection and Peritonitis. 1st
Sulfamylon and Streptomycin. Case Demonstration.
EDWARD L. HOWES.

Laboratory Experiments and Clinical Results with Bac-
tracin. FRANK L. MCELROY.

Acute Appendicitis Over a Thirty Year Period at Uni-
versity Hospital. RUDOLPH N. SCHULLINGER.

PRESBYTERIAN HOSPITAL NEUROLOGICAL INSTITUTE

9:00- 00. Neurosurgery Operative Clinic Cases Pre-
viously Shown Clinically at the Tuesday Morning
Staff Conference.

PRESBYTERIAN HOSPITAL

SLOANE HOSPITAL FOR WOMEN

9:30- Obstetrics and Gynecology Operative Clinic
Wertheim Operation for Carcinoma of the Cervix.
HOWARD C. TAYLOR, JR.

1:00- Obstetrics and Gynecology Nonoperative
Clinic Trends in the Treatment of Uterine Carcinoma.
HOWARD C. TAYLOR, JR.

3:00- Obstetrics and Gynecology Nonoperative Clinic
Rh Factor in Obstetrics. J. GREENE.

4:00- Obstetrics and Gynecology Nonoperative Clinic
Late Follow-up Results in the Treatment of Pregnancy
A. J. TELLMAN.

PRESBYTERIAN NEW YORK ORTHOPEDIC HOSPITALS

Fracture Service

9:00- 1:00. Fractures and Traumatic Surgery Fracture
Service Grand Rounds and Conference.

1:00-4:00. Fractures and Traumatic Surgery Nonopera-
tive Clinic.

Role of Sympathetic System in the Surgery of Trauma.
The Treatment of Shock Coincident with Trauma.
JOHN SCHULDER.

ROOSEVELT HOSPITAL

9:00- General Surgery Nonoperative Clinic Tumors
of the Stomach With Colored Photographs of Specimens.
HOWARD A. PATTERSON.

Demonstration of Stomach Tumor Specimens. WALTER
BRAKETER.

Some Late Results of Conservative Treatment in Vascu-
lar Problems. GRANT P. PROCTOR.

The Observed Effect of Various Drugs on Intestinal Act-
ivity (Motion Picture Demonstration). DAVID M.
WICKER.

ST VINCENT'S HOSPITAL

9:00- General Surgery Operative Clinics and Demon-
stration Cases of Trauma Fractures. MACTICE,
FRANK CONWAY, LOUIS SARTMAN, JOHN A. FALLON,
MAURICE O'SHEA.

9:00- General Surgery Tumor Clinic and Follow-up.
GEORGE R. STEARNS and Tumor Committee.

9:00- Neurosurgery Nonoperative Clinic The Re-
sults of Conservative Treatment of Acute Head In-
juries. FRANKLIN ROBINSON.

1:00- Pathology Display of Fresh Pathological Mat-
erial of Systemic Diseases by Kodachrome Slides
of Fixed Specimens. ROTHSCHILD and ASSOCIATES.

SLOANE HOSPITAL FOR WOMEN

(See Presbyterian Hospital)

VETERANS ADMINISTRATION HOSPITAL

9:00- General Surgery Operative Clinic. CARLES
WEEKS, JOHN E. SULLIVAN.

9:00- Thoracic Surgery Operative Clinic. WALTER
CHANDALL, ARON HODMELSTEIN, RICHMOND MOORE.

9:00- Orthopedic Surgery Operative Clinic. STEPHEN
EICHENHOLZ, ROBERT PATTERSON, FRANK E. STEIN-
FIELD.

9:00- Head and Neck Surgery Operative Clinic.
EDGAR L. FRANKEL.

9:00- Plastic Surgery Operative Clinic. HERBERT
CONWAY.

9:00- Radiation Therapy Exhibit and Presentation
Bronchogenic Carcinoma—Analysis of Diagnosis and
Therapy with End Results. A Study of 600 Cases.
ARON SHERIDAN, BERNARD ROSENTHAL, JOSEPH STEIN
and RESIDENT STAFF.

9:30- 1:30. Medical Rehabilitation Clinic. HARRY KIN-
SLER, KARL HANFINGER, IRWIN D. STEIN, BERNARD
STULL, JACOB BYER.

1:00- General Surgery Nonoperative Clinic: Tho-
racolumbar Sympathectomies. CARLES WEEKS.

3:00- Plastic Surgery Conference: HERBERT CON-
WAY, CLARENCE R. STRAUSSER, CORNELIUS J. KRANTZ,
ROBERT H. CHAFFORD and RESIDENT STAFF.

3:30- Anesthesia Section. Conference: Endotracheal
Intubation. Electrocardiographic Changes During
Intrathoracic Surgery. EMERY ROYCE, HAROLD
BISHOP, CHARLES BURSTEIN and RESIDENT STAFF.

EXHIBITS

Anesthesia Section	Results of Vagus Section
Bronchogenic Carcinoma	Pathology Section
Review of 600 Cases	Medical Illustrations
Intracranial Neoplasms	Laboratory
Residency Training Program	Plastic Surgery
Organization of Surgical	Prosthetic Appliances
Division	

CLINICS IN BROOKLYN—LONG ISLAND HOSPITALS

Friday

CUMBERLAND HOSPITAL

- 9:00-12:00. *General Surgery* Operative Clinic. Cancer and Prostate. HOWARD T. LAMOWORTHY and STAFF
Orchiectomy for Prostatic Metastases. Late Results.
Cancer of Bladder with Transplantation of Ureter. Late Results. LEO DREKLER and STAFF
12:00-5:00. Nonoperative Clinic. Diagnosis and Management of Ureteral Calculus, Results in 255 Cases. FRANK C. HAMM.
Late Results in Thrombophlebitis and Phlebothrombosis. WARD CIELLY
Tumors in Children. HERMAN CHARACH.
Convulsions During Anesthesia. Late Results
Late Results in Surgical Jaundice.

KINGS COUNTY HOSPITAL

- 9:00- *Gynecology* (Kings County Division) Operative Clinics. GARLICK, McGOLDRICK and MUELLER.
9:00- *Thyroid Surgery* Operative Clinic. Thyroidectomy. ANTHONY PIRRODDI
9:00- *General Surgery* Nonoperative Clinic. JOHN F. RAYCROFT and STAFF
Cholecystectomy in the Acute Gall Bladder as Compared with Cholecystectomy in the Chronic Gall Bladder. IRWIN P. TRAM
Use of the Miller Abbott Tube As an Aid in Intestinal Surgery. JOHN F. RAYCROFT

- Review of Gastric and Duodenal Surgery. HARVEY F. POTTER.
Fracture of the Neck of the Femur—Five year Study with Follow-up. VINCENT S. MAGGIO.
Case Report. Congenital Idiopathic Dilatation of the Common Bile Duct. JOHN F. RAYCROFT
Review of Amputations of the Lower Extremities. THOMAS W. HYMAN.
Review of Acute Appendicitis. PETER FIORE.
Review of Large Bowel Surgery. BERNARD J. FICARRA.
Therapy of Peripheral Vascular Disease. C. BURLING ROESCH.
10:00- *Thyroid Surgery* Nonoperative Clinic. Use of Propyl Thiouracil.
12:00- *Gynecology* Nonoperative Clinic. Follow up of Gynecologic Malignancies. JOSEPH MCGOLDRICK.

LONG ISLAND COLLEGE HOSPITAL

- 12:00- *General Surgery*
Operative Program. EMIL GOETSCH and STAFF
Fractures and Other Trauma. S. POTTER BARTLEY
HAROLD LAROE.
Diagnostic and Therapeutic Nerve Blocks. PAUL ANSERO.

METHODIST HOSPITAL

- 9:00-12:00. Tumor Clinic (Late Results). PIERRE A. RENAUD. Moderator and Hospital Staff

THE CLINICAL CONGRESS TECHNICAL EXHIBITION

LEADING manufacturers of and dealers in surgical instruments, hospital apparatus and supplies, diagnostic and therapeutic apparatus, pharmaceuticals, and publishers of medical and surgical books will be represented in the Technical Exhibition at the Waldorf Astoria Hotel, New York, September 8-12 1947

Exhibitors

- Abbott Laboratories, North Chicago
 Acme Engineering Co., Inc., Greensboro, N. C.
 A. S. Aloe Company St. Louis
 American Cystoscope Makers, Inc., N. Y.
 American Hospital Supply Corp., Evanston, Ill.
 American Safety Razor Corp., Brooklyn
 American Sterilizer Company Erie, Pa.
 Ames Company Inc., Elkhart, Ind.
 D. Appleton-Century Company Inc., N. Y.
 Armour Laboratories, Chicago
 The Gordon Armstrong Company Cleveland
 Anatal Laboratories, Inc., N. Y.
 C. R. Bard, Inc., N. Y.
 Bard-Parker Company Inc. Danbury Conn.
 W. A. Baum Company Inc., N. Y.
 Rudolph Beaver (Walsham, Mass.)
 Becton, Dickinson & Co. Rutherford, N. J.
 Julius Berbeck & Sons, Inc., N. Y.
 The Borden Company N. Y.
 Bristol Laboratories, Inc., N. Y.
 Burdick Corp., Milton, Wis.
 Cameron Surgical Specialty Co. Chicago
 Wilmot Castle Co. Rochester N. Y.
 Ciba Pharmaceutical Products, Inc. Summit, N. J.
 Clay Adams Company Inc., N. Y.
 Coca-Cola Co. Atlanta
 Cochran Physicians Supplies Inc., N. Y.
 Crescent Surgical Sales Co. Inc., N. Y.
 Cerville Products, Inc., Fort Chester N. Y.
 Cutter Laboratories, Chicago
 Davis & Geck, Inc., Brooklyn
 F. A. Davis Co., Philadelphia
 Davol Rubber Co., Providence
 J. A. DeKanel & Son, Inc., Queens Village, L. I.
 De Puy Mfg. Co., Warsaw Indiana
 Duke Laboratories, Inc., Stamford, Conn.
 F & J Manufacturing Co., Glendale, Calif.
 Ethicon Suture Laboratories, New Brunswick, N. J.
 General Electric X-Ray Corp., Chicago
 General Foods Corporation, N. Y.
 Gruno & Stratton, Inc., N. Y.
 Gudebrod Bros. Silk Co. Inc. N. Y.
 Fred. Haslam & Co., Inc., Brooklyn

COLLECTIVE REVIEW

THE ETIOLOGY OF THE ONSET OF LABOR

HOWARD STEPHEN MORROW A.B. M.D., D.M.S., Chicago, Illinois

INTRODUCTION AND HISTORICAL

AVICENNA has said that at the end of 9 months labor occurs by the grace of God" (Kurzrok). Four centuries before the Christian era, Hippocrates attributed the onset of labor to a decline in the nutritional status of the fetus (Findley). At that time he said "When there is no more food for the young one in the egg and it has nothing on which to live, it makes violent movements, searches for food, and breaks the membranes. The mother perceiving that the embryo is vigorously moving smashes the shell," and in reference to mammals

"In just the same way when the child is grown big and the mother cannot continue to provide him with enough nourishment, he becomes agitated, breaks through the membranes and incontinently passes out into the external world free from any bonds. In the same way among the beasts and savage animals, birth occurs at a time fixed for each species without overshooting it, for necessarily in each, nourishment will become inadequate. Those which have least food for the foetus come quickest to birth and vice versa. That is all that I had to say upon the subject (Needham Reynolds). According to Hippocrates, the child presses its feet against the fundus uteri and its head against the cervix, thus opening the uterine orifice (Gunn).

Despite the advances of medical science, a complete understanding of the cause of the onset of labor is lacking. A great deal is known about

the intimate details of the mechanism of labor but, other than conjecture almost nothing is known about what actually starts uterine contractions.¹

In the following review every attempt has been made to include all articles in the voluminous literature on the onset of labor from January 1938 to June, 1946. Pertinent articles have been included whenever deemed necessary regardless of date or subject, but no attempt has been made to include all articles on other however related subjects.

SUMMARY OF CURRENT TEXTBOOK OPINION

DeLee mentions, as causes of the onset of labor excessive distention of the uterine wall, the presumptive influence of the menstrual cycle so that labor occurs after 10 cycles, pressure of the presenting part on the lower uterine segment and cervix, the importance of accidental causes, and endocrine effects. Greenhill has added more details of the hormonal aspects of the problem to DeLee's original text. Mention is made of the sensitization of the uterus to pituitary extract by estrogens, its increasing activity under the influence of estrogen, and the antagonistic effects of progesterone. The use of massive doses of estrogens to induce labor in missed abortion and missed labor with dead fetus is stressed.

Williams-Stander lists the growing irritability of the uterine musculature, progressive distention of the uterus, dilatation of the cervix by the presenting part, distention of the lower uterine segment and the surrounding nervous structures,

¹Submitted in partial fulfillment of the requirements for the Degree of Doctor of Medical Science.

From the Department of Obstetrics and Gynecology of the College of Physicians and Surgeons of Columbia University and the Sloane Hospital for Women, New York, New York. The review covers the period from January 1938 to June, 1946.

excess of carbon dioxide and lack of oxygen in the placental blood which act on nervous structures or contribute to such changes in the decidua as loosening thinning and thrombosis menstrual periodicity the questionable anaphylactic action of fetal blood heredity and habit, senility of the placenta, metabolic changes, and the importance of autacoids. In his latest text Stander has included the work of Bourne and Zuckerman on the establishment of artificial estrous cycles in castrate rats. Stander suggests that the adrenals may cause the cyclic pattern resulting from the continued administration of small doses of estrogens to castrate women.

Reynolds has done more than any other individual to illuminate the previously confused field of uterine physiology. He believes that the onset of labor is the result of the gradual accelerating co-operation of a number of factors—anatomic, physiologic, humoral, nervous, nutritional, and circulatory—which at a time characteristic of the species are so associated as to lead to the evacuation of the uterus. His contributions will be discussed in greater detail later.

EXISTING HYPOTHESES ON THE CAUSE OF THE ONSET OF LABOR

The existing hypotheses regarding the cause of the onset of labor may be arbitrarily divided into three groups for the purposes of discussion: (1) chemical, (2) mechanical, and (3) hormonal. These three groups overlap and it is impossible to clearly allocate specific articles to any one of the groups.

REVIEW OF THE LITERATURE ON CHEMICAL THEORIES

In a recent review Danforth and Ivy attribute the start of parturition to the combined synergistic resultant of increasing uterine distention, alterations in the ionization of calcium and other essential ions, and the control of autacoids. They mention the effect of variations in endocrine balance, especially estrogen level upon blood calcium fixed base, and calcium ionization. Danforth and Ivy believe that as the estrogen level rises toward term calcium ionization increases and produces the known increase in uterine irritability. This, together with growing uterine distention, causes the beginning of uterine contractions. Calcium ions thus act as an intermediary between the autacoids and their uterine endorgan. They point out, however, that at present no scientifically accurate method exists for the precise mensuration of calcium ionization and state that the final proof of their interesting conception awaits such a method. Other authors concur as

to the importance of chemical factors in uterine activity and labor (Wattenwyl, Karnaky Reynolds).

A survey of the literature on calcium ionization reveals considerable discrepancy of opinion regarding its determination (Chu and Hastings, Correll and Hughes, Dillman and Vischer, Drinker *et al.*, Eversole *et al.*, Eversole, Fales, Greenberg and Gunther, Hammett, Hitchcock, Hughes *et al.*, Ingraham *et al.*, Kendall Smith and Sternberger, Thomas, Yarnot). Several authors have used collodion membrane ultrafiltration (Greenberg) followed by barium sulfate adsorption (Benjamin, Benjamin and Hess). The latter procedure is of doubtful value (Greenberg, Greenberg and Larson) despite statements to the contrary (Benjamin). Other techniques for the determination of calcium ions depend upon high pressure ultrafiltration through cellophane membranes (Nicholas), electrodes of the third kind (Joseph), ultracentrifugation (Chanuth *et al.*, Ludewig *et al.*, Masket *et al.*), empirical formulas of varying degrees of exactness and clinical applicability (Rona and Takahashi, McLean and Hastings, McLean and Hinrichs, Morrison *et al.*, Gutman and Gutman) and biological indicators of moderate accuracy such as the frog heart (McLean and Hastings, Morrison *et al.*, Spelman) and the guinea pig uterus (VanDyke and Hastings).

The formula of Rona and Takahashi is one of the simplest and forms the basis of the later mass law equations of McLean and Hastings and others. It was later modified to

$$\frac{(\text{Ca}^{++}) \times (\text{Protinate}^-)}{\text{Ca Proteinate}} = K$$

(McLean and Hastings)

The original references contain chemical constants and other data. VanDyke and Hastings state "Changes in the response of the (guinea pig) uterus to constant doses of pituitary extract when placed in solutions in which all of the ion concentrations, except calcium, have been constant, have been interpreted as indicating differences in calcium ion concentration in the solutions. In a sense the uterus has been a biological calcium electrode." They note that changes in the carbonate ion activity and calcium ion concentration cause the greatest changes in activity of the isolated guinea pig uterus.

The calcium ion concentration in serum is quoted as varying from 2 to 6.4 mgm. per cent. The higher figures (3 to 6 mgm. per cent) are the more probable (Schmidt and Greenberg, Updegraff *et al.*). In an exhaustive review Schmidt and Greenberg remark that a very large part of the

evidence offered for the existence of calcium compounds other than ordinary calcium ion in the diffusible fraction of blood serum is either insufficient incorrectly interpreted or in many instances, quite incorrect and later The follicular hormone is said to increase the serum calcium concentration of castrated animals. More will be said of this later but suffice it to say here that the experimental results on the ionization of calcium are quoted with great frequency in the medical literature (Best and Taylor Peters and VanSlyke Danforth and Ivy Bodansky) despite their relative inaccuracy.

There is an increase of diffusible ionized calcium and a decrease of total serum calcium in the latter part of pregnancy and labor (Cantarow *et al* Bodansky and Bodansky Bodansky and Duff Zwarenstein, Nicholas *et al*) It is possible that the growth of the ionized fraction is a relative and not an absolute expansion (Andersch and Oberst).

Thus, blood calcium is divided into diffusible and nondiffusible fractions. The diffusible or ultrafiltrable fraction is entirely ionized whereas the nondiffusible or nonfiltrable fraction is largely protein-bound in the form of calcium proteinate. The methods for measuring calcium ionization are scientifically inaccurate. Direct methods do not exist and indirect means are employed. The invention of a suitable calcium electrode (a direct way) would end the present controversies and permit clarification of the problem of the relation of physiologic calcium ionization to uterine activity.

Considerable doubt exists that continued massive estrogen dosage will affect the serum calcium of mammals (rat rabbit monkey) (Levin and Smith) as it will of other animals, notably the chicken (Heller *et al* Avery *et al* Bremer Lan dau *et al* Zwarenstein, Schmidt and Greenberg Correll and Hughes) other than transiently. Despite the well known antagonism of androgens and estrogens injection of either androgenic or estrogenic substances into patients with skeletal metastases from mammary carcinoma increases metastatic growth and raises serum calcium and urinary calcium (Farrow and Woodard) Skeletal bone resorption or osteoclastosis follows massive estrogen dosage in mice (Gardner and Pfeiffer) while osteitis fibrosa cystica results from similar treatment of rats (Bremer) Estradiol benzoate injections into immature mice for many weeks cause osteoclastosis of the long bones and pubic bone resorption. The higher dosages give rise to greater sclerosis (Sutro) Prolonged administration of estradiol benzoate to young dogs produces inhibition of skeletal growth but no osteoclastosis

(Sutro and Pomerantz) Hypercalcemia is the standard toxic reaction to ergosterol (Hess *et al*) A transitory rise in the calcium content of the immature rat uterus is found following single massive dose estrogen injections (Talbot *et al*) while estrone has no effect on uterine anaerobic glycolysis (Sweeney) The lowered serum calcium found after the middle trimester in pregnancy (Bodansky and Bodansky Bodansky and Duff) may perhaps be correlated with rising levels of estrogen and progesterone.

Numerous investigations have conclusively shown that ionic calcium increases the activity of the uterus of the dog guinea pig and rabbit (Danforth and Ivy Rouse and Blanchard Okai, Johnson Greig) This also holds for smooth muscle in general (Evans) and presumably for the human uterus (Reynolds) A calcium deficient diet in the kod and chick produces a defect in neuromuscular transmission, such that a single maximal motor nerve volley fails to elicit a maximal response from the muscle in question (Brown and Harvey) Either excess or deficiency of ionized calcium results in neuromuscular block in frog nerve-muscle preparations (Kuffler) The presence of ionized calcium is essential for uterine contractions (Ivy).

Magnesium increases the response of the guinea pig uterus to posterior pituitary extract (Fraser) but reduces its general activity (Reynolds) while magnesium and potassium are antagonistic to calcium as regards the uterus (Reynolds) Magnesium ion exerts an immediate spasmolytic effect upon the tetanic human uterus. It abolishes tetany due to pituitrin pitocin pitressin quinine ergonovine, or methergine. It is useful in the tetany of spasmodic dysmenorrhea, afterpains and dystocia (Bandring) (Abarbanel).

Since the blood strontium level is normally extremely low (Fay *et al* Cole *et al*) it may be assumed that its normal physiologic activity is nil. Nevertheless, its activity is greater than that of calcium as an experimental uterine muscle stimulant (Cole *et al* Cole Harned and Cole Fay *et al* McCance and Widdowson) On the whole its toxicity is less than that of calcium (Cole *et al* McCance and Widdowson).

The production of histaminase by the placenta has been correlated with uterine contractions and placental aging more histaminase is produced when there are poor contractions, less when the contractions are stronger. The amount of histaminase found is in no way directly related to uterine contractions but rather is an index of the amount of active functioning parenchymatous tissue in the placenta. Physiologic senescence is a salient factor in the onset and maintenance of

labor (Danforth) (See Mandel *et al*) The blood pressure falls with each uterine contraction in pregnant cats. The hypotension has been attributed to the rhythmic production of histamine by the placenta, which causes both uterine contractions and blood pressure fall (Handovsky)

Oxygen consumption of the human placenta falls in pregnancy presumably because of senescence (Wang and Hellman) There is no correlation between placental senescence and the onset of labor (Mandel *et al*) Oxygen supply to the fetus is greatest during uterine contractions (Windle and Steele, Barcroft *et al*) During labor pains effective maternal arterial pressure to the placenta diminishes—sometimes to zero (Woodbury *et al*) This may cause additional placental aging during labor (Mandel *et al*)

Amniotin, estradiol, estradiol benzoate, estradiol dipropionate, and triphenyl ethylene (a synthetic estrogen) increase within an hour the acetylcholine content of the uterus of the ovariectomized rabbit (Reynolds and Foster Reynolds) There is the same amount of acetylcholine in the uteri of both estrogen treated and untreated spayed rabbits (Emmens *et al*) The blood choline concentration does not appreciably vary in pregnancy labor and the puerperium (Eagle) Acetylcholine has been suggested as the normal causal oxytocic agent in labor (Reynolds)

There is a definite shortening of the duration of labor following the prolonged use of a salt-poor diet in pregnancy This may be due to the reduction of uterine muscle edema on such a regimen (Pomerance and Daichman Wadlow Schuitens, Balasgride)

Summary and conclusions The rising levels of sex steroids in pregnancy cause a progressive increase in calcium ionization, uterine irritability, contractility and motility Calcium ions are essential for normal uterine muscle irritability, contractility and motility The periodic uterine muscle contractions occur with growing strength, co-ordination, and frequency throughout pregnancy because of the synergistic action of the sex hormones and the concomitant rise in the concentration of calcium ions The basic mechanism here is hormonal the secondary assisting and co-operating factor is chemical.

The hormonal mechanism can produce uterine contractions and labor with a normal, or even a low level of calcium ionization. The heightened concentration of calcium ions at term assists the endocrines in bringing about parturition but is in no wise a causal factor alone. Calcium ions do not mediate between the autacoids and uterine muscle they merely provide part of the essential

physiologic environment which permits response of uterine muscle to sex steroids, acting in this sense like any other tissue metabolite.

REVIEW OF THE LITERATURE ON MECHANICAL THEORIES

Uterine distention is an important factor in the determination of uterine growth uterine contractions, and, eventually parturition. The distention-growth response (hyperplasia and hypertrophy) in the uterus of the ovariectomized rabbit is dependent upon maturity because it does not occur in immature rabbits with uteri distended with paraffin pellets. It also does not occur in estrin treated ovariectomized rabbits, but it appears in those treated with progesterone. Progesterone increases the tolerance of uterine muscle to distention, because the growth stimulus must be greater (more distention) to produce the same growth as in nonprogesterone-injected ovariectomized rabbits (Reynolds) The intrauterine pressure does not differ greatly in normal and hydramniotic pregnant women, and the rise in intrauterine pressure is not proportional to uterine expansion. The pressure in the uterus before labor is practically nil (Wieloch) The intrauterine pressure bears no relationship to either the volume of the uterus or the amount of amniotic fluid. In primiparas the intrauterine pressure is inversely proportional to the duration of labor (Salerno)

The motility of the uterus in vivo has been studied by means of intrauterine insufflation with variations recorded by a kymograph (Rubin, Mayer *et al*) intrauterine balloons (Bickers, Wilson, Wilson and Kururok) extrauterine devices such as the Lorand tocomograph (Lorand, Murphy) electrically (Fenning *et al*) Katzenstein, Katzenstein and Soskin, Jacobson *et al*, Langman and Burr Border Balassa and Gurd) and in experimental animals by means of mechanical lever systems (Clausberg Reynolds) In addition, studies in vitro have been made of the entire excised uterus or uterine strips (Sun, Adair and Haugen) It is probable that all in vitro observations on any uterus are misleading (Bell) Furthermore, observations on the primate uterus are far more reliable than those made on other species, as regards significance for the human (Hartman)

The uterus demonstrates increased activity under the influence of estrogens (Knaus, Novak, Falls, Adair and Haugen, Murphy Wattenwyl, Langman and Burr Krohn *et al*) and decreased activity under the influence of progesterone (Reynolds, Knaus, Novak, Falls, Langman and Burr Krohn *et al*) Opposed to this viewpoint is the

demonstrated synergism between progesterone and estrogen, with heightened uterine activity and co-ordination in the luteal phase of the menstrual or estrous cycle (Wilson and Kurzrok, Bell, Bell and Robson, Page and Woods, Bickers, Bickers and Main Henry and Browne). Clinically, the uterus becomes quiescent in patients with threatened abortion or labor treated with progesterone (Falls, Falls *et al* Krohn *et al*). Experimentally the human uterus does not respond to progesterone *in vivo* (Bickers, Page and Woods). Greater uterine activity and co-ordination in the luteal phase are also suggested by anatomical and endocrine studies on the endometrium and mucosa of the vagina (Hartman, Bartelmez, Markee, Engle).

The uterine motility of the guinea pig undergoes a cycle characterized by lowered amplitude and greater frequency of contractions during the time of activity of the corpus luteum. The immediate cause of this variation appears to be an impairment of conduction of the contraction wave between the ovarian and vaginal ends of the uterus. Alterations of the calcium content of the uterine bath appreciably affect the motility cycle and may mask it entirely (Greig). Progesterone does not alter the uterine activity induced by stilbestrol (Lackner and Tulsky). Testosterone propionate acts like combined estrogen-progesterone in producing characteristic uterine motility patterns in castrate women (Wilson and Kurzrok).

Neither spontaneous uterine activity nor response to injected oxytocin in spayed mice treated with estrone is modified by either testosterone or progesterone. Progesterone does not desensitize the mouse uterus to injected oxytocin *in vivo* (Bell and Robson). These findings have been confirmed in the spayed rhesus monkey (Bell). The degeneration of the corpus luteum at the fortieth day of pregnancy in the guinea pig corresponds with the middle of the transition period from low to high reactivity of the uterus to oxytocin *in vivo* (Bell). This partially corresponds with the results obtained in the human with external and internal hysterography *in vivo* (Bickers, Murphy, Fenning) and with observations on the human uterus and uterine strips *in vitro* (Adair and Haugen, Sun). Uterine tetany disappears after rupture of the membranes during labor. Spontaneous contractions cease after the tenth day of the puerperium as do the responses to pituitrin, paralleling the fall in the concentration of blood estrin. A certain degree of intrinsic uterine motility can be restored by the administration of estrogen while the uterus again be

responsive to pituitrin. The practical value

of this observation in puerperal hemorrhage occurring after the fifth day is apparent (Bickers).

Under the influence of emotional stress, the human uterus displays its greatest activity during the pregestational phase of the menstrual cycle (Robertson). On the other hand, electrometric studies reveal that in castrate women uterine activity is reduced by progesterone and intensified by estrogen (Langman and Burr). In the rat uterus there is a correlation between electrical chronaxie and phases of the estrous cycle. The highest excitability shortest chronaxia is found in estrus, while estrogen therapy heightens excitability to levels comparable to those found in spontaneous uterine estrus. It is possible that the ovary elaborates an inhibitory substance which cyclically decreases excitability; this is felt to be distinct from progesterone (Katzenstein, Katzenstein and Soskun) (also see Bourne and Zucker, DiPaola). Injection of estrone into the cat and rabbit produces an increase in electrical excitability and resting potential of the uterus. Responses of the isolated uterus are local during anestrus (muscular movements weak and incoordinated) but conducted during estrus (entire uterus involved in contraction wave). These changes in excitability which are not truly comparable to chronaxia make explicable the changes in uterine motility during the sexual cycle (Boaler). Electrical potentials in the cat uterus are most active in estrus and late pregnancy least active in early pregnancy or during pregestational proliferation. Conduction of impulses from cell to cell is characteristic of estrus (Balassa and Gurd). The uterus relaxes after parenteral administration of corpus luteum extract to the human being; this has been recorded simultaneously electrically and with an intrauterine balloon (Jacobson *et al*). In human beings, pregnancy is merely a continuation of the luteal phase of the menstrual cycle in which maximum amplitude of uterine contraction waves is reached at the onset of menstruation (Wilson).

Reynolds has commented upon the fact that excessive distention alone will produce uterine motility during any phase of the menstrual cycle. He believes that pressures above 20 mm of mercury produce artifactual motility when intrauterine balloons are used, and, therefore that the work of Knaus, who did not use pressures above 20 mm is most reliable. However Bickers and Main point out that no amount of distention will stimulate contractions in the castrate unless the uterus is first sensitized by estrogens. Moreover according to McLellan alterations in the distending pressure do not necessarily alter spontaneous

contractions or reactivity to pituitrin, while a pressure above 20 mm. of mercury is necessary to ensure proper recording.

The opposing schools may perhaps be reconciled by noting that low amplitude, high frequency, somewhat tetanic contractions are characteristic of the normal uterus during the follicular phase while higher amplitude, lower frequency contractions devoid of tetany are characteristic of the luteal phase. In anovulatory cycles the follicular type of contraction prevails throughout, while there is temporary abolition of intrinsic motility during coitus (Bickers and Main).

The human uterus contracts rhythmically throughout life from before birth until after the menopause. The contractions differ in different pregnant individuals, during labor and in the puerperium. There are no spontaneous contractions in the lower uterine segment, which does not contract except in response to pituitrin. This peculiarity may conceivably lead to uterine rupture because the upper and lower uterine segments act against one another when under the influence of posterior pituitary extract. The spontaneous contractions of the upper uterine segment correspond to the Braxton-Hicks contractions and afterpains of the post (Sum).

An increased frequency of response to pituitrin occurs in multigravidas rather than primigravidas, during labor rather than before labor later in pregnancy than earlier after the larger does rather than the smaller ones, and when the uterine wall is tense rather than when it is relaxed (Murphy). The tetanic type of response is most often observed when the dose is large and tension of the uterine wall high. The uterus becomes most active and reactive to posterior pituitary extract during the week or two immediately preceding clinical labor. Uterine activity grows progressively during pregnancy, the greatest augmentation occurring in the middle of pregnancy at the thirty-second week. Patients with uterine contractions prior to the thirty third week are apt to have shorter labors. Multigravidas and patients with short labors are likely to have contractions during late pregnancy which are less frequent, more rhythmic, stronger and longer in duration than primigravidas and individuals with longer labors (Murphy, Fenning, Robson and Schild). The heightened rapidity and strength of response as pregnancy advances may indicate that a posterior pituitarylike hormone is elaborated which potentiates the effect of injected posterior pituitary extract (Murphy).

The percentage of positive reactions of human uterine muscle strips *in vitro* is higher to pitressin

than to pitocin in both gravid and nongravid uteri (Adair and Haugen). *In vivo*, however, oxytocin causes muscular contractions of the uterus but has little or no effect on the blood flow through the uterus, whereas vasopressin always decreases the blood flow whether or not it causes a relaxation (Robson and Schild). Vasopressin exerts a direct inhibitory action on uterine muscle (Robson and Schild). The uterus responds to posterior pituitary extract immediately before and during menstruation and in the early interval part of the cycle. The nongravid human uterus is caused to contract by vasopressin and not at all by oxytocin (McLellan). The uterus of the castrate woman is quiescent and insensitive to pituitrin, intrinsic motility and sensitivity to pituitrin are restored by estrogen. In cases of missed abortion with a negative Friedman test the uterus is quiescent and insensitive to pituitrin, spontaneous motility is induced by estrogen and the sensitivity to pituitrin is re-established, which permits evacuation of the uterus (Bickers and Main).

Uterine tonus rises progressively as pregnancy continues, but during the last lunar month less than 50 per cent of the patients have measurable tonus. On the other hand, very high tonus has been recorded in a patient with abruptio placentae undergoing labor. The contraction pattern in false labor resembles that in true labor, no distinguishing traits have been observed. The uterine contraction pattern of normal labor is described as (a) contractions of appropriate magnitude, (b) relatively high degree of rhythmicity and (c) contractions which resemble one another closely in magnitude and general character. Primary inertia, on the other hand, is distinguished by a contraction pattern of (a) contractions of small magnitude, (b) arrhythmicity of occurrence of successive contractions, and (c) contractions which fail to resemble each other in magnitude and general character (Murphy). The original observation of Lownd that primary uterine inertia consists of three categories—normotonic, hypotonic, and hypertonic—has been confirmed by Murphy.

The advance of labor produces progressive increases in uterine tonus, strength of intermittent contractions, total amount of energy expended, and frequency of contractions, while the duration of contractions shortens. Primiparas experience a higher tonus during labor than do multiparas, while multiparas experience stronger contractions than do primiparas. Dystocia augments the already high tonus of primiparas and the already strong contractions of multiparas. It prolongs the duration of contractions of all patients. Poor

uterine motility is not the important factor that determines the direction of rotation of an occiput which engages in the posterior position (Murphy) Labor is almost universally accompanied by intermittent contractions but may proceed to completion in the absence of such contractions if uterine tone is persistently high. Labor never occurs in the absence of both intermittent contractions and a persistently high uterine tone. Intermittent contractions are not indispensable to the process of labor and do not play a significant role in deciding the length of the first stage of labor (Murphy). Continuous caudal analgesia causes a successive decrease in uterine tone in 44 per cent of patients examined. Only 20 per cent of patients have any lessening of uterine motility if the level of analgesia does not rise above the sixth to tenth thoracic segment (Frankel).

Morphine has no effect on uterine contractions (Murphy, Adair and Pearl). Morphine sometimes strengthens, sometimes weakens uterine contractions (Gunn). The uterine musculature is not directly affected by the doses of morphine commonly used in obstetric analgesia (Goodman and Gilman). Morphine causes a disturbance of the mechanism of labor and a prolongation of labor in the rabbit, but does not directly affect fetal respiratory exchange (Snyder and Geiling).

Benzedrine sulfate produces a prolonged spastic contraction of uterine strips from the virgin guinea pig (Boyd). The uterus of all animals are contracted by benzedrine (Goodman and Gilman). Epinephrine causes inhibition of uterine muscular contractions in the guinea pig (Boyd). The human uterus usually contracts in response to epinephrine, whether gravid or nongravid (Goodman and Gilman, Adair and Haugen, Gunn).

Parturition occurs normally independent of or in the absence of innervation to the uterus (DeLee, DeLee and Greenhill, Williams-Stander, Stander, Whitehouse and Featherstone, Elkin, Blittman, Danforth and Ivy, Reynolds, Salgado). Direct observation of the uterus under spinal anesthesia suggests that the action of the central nervous system on the human pregnant uterus is one of sustained inhibition. This inhibition is most pronounced before the sixteenth week and reappears near term (Mifalpas).

The lower uterine segment or isthmus uteri is evident at 3 months of pregnancy below the physiologic retraction ring or Aschoff's anatomic internal os. The first stage of labor is accompanied by retraction of the isthmus uteri, the second stage by retraction of the cervix. High retraction of the cervical lips characterizes labor in man and monkey. Retraction is essentially the same process in

both upper and lower segments. Most of the expulsive work of the uterus in labor is performed by the upper segment. The so-called thinning out of the isthmus uteri does not occur in the monkey, and may not occur in man. Separation of the placenta is almost completed by the end of the second stage of labor in the monkey and presumably in man (Danforth, Danforth and Ivy, Danforth *et al.*, Ivy, Ivy and Rudolph).

Retraction is an economical and relatively non-energy consuming process whereas contraction is an energy consuming process. Retraction or brachystasis is a relative fixation of a muscle at shorter length; the muscle shortens and at the shorter length manifests the same tension. Mectomy is a relaxation or elongation of muscle fiber at the new length it manifests the same tension. These mechanisms permit enlargement of the uterus to adapt itself to the growing fetus without change in intrauterine tension (Ivy, Danforth and Ivy, Danforth *et al.*, Ivy and Rudolph, Wieloch). Beyond a certain point however this does not hold and the effects of distention upon uterine muscle are seen (Reynolds).

Summary and conclusions. The sequence of events leading toward the beginning of labor includes the factor of increasing uterine distention. This distention progressively heightens the efficiency of uterine contractions, in conjunction with the steadily rising output of placental estrogens. Brachystasis and mectomy of the uterine musculature concomitant with rising progesterone levels permit uterine enlargement without significant alteration in intrauterine pressure. Estrogen and progesterone synergistically co-ordinate uterine activity and stimulate spontaneous uterine contraction and intensify reactivity to posterior pituitary secretion. Development of the lower uterine segment proceeds toward term at which time it actively participates in labor. Successive increases in uterine tone and in the strength, duration, and frequency of uterine contractions occur. The onset of labor is physiologically concomitant with (1) optimal uterine distention, (2) high uterine irritability, (3) complete development of the isthmus uteri, (4) strong frequent, spontaneous and co-ordinated contractions of the corpus uteri, (5) high uterine muscle reactivity to pituitrin and (6) effective uterine inhibition by the central nervous system.

REVIEW OF THE LITERATURE ON HORMONAL THEORIES

The earlier conception of Hippocrates that the onset of labor is due to a decline in the nutritional status of the fetus is not altogether fanciful. A

decline in fetal nutrition or oxygen supply may cause the fetus to produce a fetal hormone that initiates parturition (Gibbons). On the other hand, studies of the reserve capacity of the placenta show that it is more than sufficient for fetal needs, even in the presence of severe infarction (Williams-Stander Mandel *et al*). In addition, removal of the fetus alone with the placenta left viable and *in situ* does not prevent gestation from proceeding to term, while labor occurs at the normal time (Reynolds, Newton and Lits, Newton and Beck, Kirsch Deanesley and Newton, Murphy). The placenta (alone) is necessary for labor (Ivy). The mechanism for the continuation of pregnancy in the mouse is the maintenance of the corpus luteum by the placenta (Deanesley and Newton). The preservation of body weight and reabsorption of the symphysis pubis in the presence of the retained placenta occur normally in the absence of the pituitary in the mouse whereas the ovaries must be present (Newton and Beck). The presence of the placenta in the mouse sustains mammary development in the absence of the ovaries (Newton and Lits).

The nonessentiality of the posterior hypophysis for normal pregnancy and labor has been frequently demonstrated (Reynolds, Dixon and Marshall, Flör Kurzrok, Novak, Robson, Smith White, Allen *et al*). The hypophysis is not necessary for labor (Ivy). These experiments have not been repeated in primates (Hartman) and considerable evidence to the contrary exists (VanDyke Ferguson, Haterius and Ferguson, Fisher *et al* see Hartman *et al*).

There is an oxytocic substance in the blood and urine of pregnant and parturient women which may be identical with extract from the posterior pituitary lobe (Fontes, Gibbons, Brdiczka Chang *et al*, Kurzrok, Clauberg). No such oxytocic entity can be demonstrated by the action of pregnancy serum on the human nonpregnant uterus (Lackner and Tulaky). A recent repetition of the earlier experiments of Fontes, with serum from normal men nonpregnant women gravid women, and parturients, has resulted only in a nonspecific oxytocic effect by all sera on reacting uteri of the nonpregnant guinea pig *in vitro*. A protein-free serum filtrate has been without influence on any of the uteri (Graff *et al*, Jeffcoate). The only good evidence for the hormonal activity of the posterior lobe of the hypophysis is the result of its extracts on the uterus (Reynolds). Certain experimental conditions cause the release of oxytocin from the posterior pituitary lobe (Chang *et al*, Fisher *et al*, Ferguson, Haterius and Ferguson VanDyke). The identity of the supposed oxytocin

in the blood and urine of pregnant and parturient women has yet to be established (Reynolds) but it appears to be identical with extract from the posterior pituitary lobe (Clauberg). A rising concentration of melanophore expanding principle in the blood serum during pregnancy reaching its highest level during labor and disappearing in the puerperium, has been described (Clauberg). While this principle is not identical with the oxytocic extract of the posterior pituitary lobe (Allen *et al* A.M.A.) a rising concentration may indicate an augmented activity of the posterior hypophyseal lobe during labor (see Robson).

The physiology of the estrogenic autacoids in the pregnant and nonpregnant animal and man has been exhaustively investigated (Allen *et al*, A.M.A. Best and Taylor Kurzrok). The coagulation reaction of the rodent vagina (Allen) and growth and edema of the rat uterus (Astwood, Pincus and Graubard, Lawson *et al* Wick and Powell) have been used as biologic standardizers of estrogenic products. The early gain in weight of the uterus in response to estrogen therapy has been shown to be due to increase in water content followed by protoplasmic growth (Reynolds, Kneer Grumbrecht and Looser). The edema of normal and toxemic pregnancies is the result of a similar phenomenon (Taylor *et al*). Estrogen causes a maximal hyperemia of the uterine vascular bed followed by a rise in uterine metabolism (oxygen consumption) and finally the initiation of uterine motility (MacLeod and Reynolds). Inflammation of the myometrium alone in the absence of ovarian hormones produces arrhythmic motility in uterine fistulas of the untreated ovariectomized rabbit. Estrin induced motility is rhythmic (Laufer and Reynolds). The highest oxygen consumption of uterine muscle occurs during estrus (Reynolds). Estrin is essential for uterine contractions and indispensable for parturition theoretically estrin administration in sufficient quantity should bring about labor. Under its control uterine contractions become increasingly co-ordinated and powerful as gestation advances. Until the latter part of pregnancy its influence is held in abeyance by progesterin, possibly also by prolactin. As uterine distention progresses, uterine contractions grow more forceful and efficient (Reynolds).

In castrate monkeys menstruationlike bleeding occurs after sudden discontinuance of a course of either estrogen or progesterone. When estrogen and progesterone are given simultaneously bleeding takes place if progesterone is discontinued even if estrogen is continued. This may be the natural mechanism of menstruation as the corpus

luteum waxes and wanes (Corner Engle Allen) The threshold for estrogen deprivation bleeding is below that for estrous growth and edema (Hartman *et al*)

In man as in monkeys estradiol is convertible to estrone and estrone to estradiol. Progesterone acts through the uterus, probably on the endometrium, to bring about estrone to estradiol conversion. Thus, the distribution of estrogens in the urine supplies an index of progesterone activity because progesterone carries the following reaction

to the right Progesterone partially protects estrogens against destruction, largely in the liver and thus permits greater use and excretion. The amount of estrogen in the urine represents a balance between production and destruction Estradiol is less active physiologically than estrone. Progesterone deficiency results in lessened conversion of estrone to estradiol, and causes the estradiol to estrone reaction to swing left, together with greater destruction of all estrogens. Progesterone deficiency exists during normal labor and delivery and thus it is possible that a precipitating factor in the onset of labor may be the consequent rise of the more active estrone (Smith *et al* Mallow Cohen *et al*)

Likewise between 8 and 24 days before labor a maximum efficiency in the production and conversion of estrogen and progesterone is reached. Between this zenith and the onset of labor a progressive change in steroid metabolism occurs distinguished by progesterone and estrogen withdrawal on account of a gradually diminishing rate of production and conversion and slightly greater destruction The onset of labor coincides with a sudden decrease in conversion and an increase in destruction Uterine contractions result in a rapid decline in the rate of estrogen and progesterone production and conversion and a rise in destruction. This has also been observed in a 5 hour period of labor artificially produced by rupture of the membranes (Smith *et al*) Maximal estrogen and progesterone excretion occurs from 8 to 10 days before parturition (Hain)

The diminished production of progesterone as term approaches (Lyon) may be due to placental senescence (Ivy) although placental reserve is more than sufficient to maintain manufacture at normal levels (Mandel *et al*) In contrast to these reports, a gradual rise of estradiol, estrone and progesterone excretion during the last weeks of pregnancy has been noted (Browne *et al* Venning

Bachman Hain) The precise relationship of autacoid metabolism to the onset of labor has yet to be determined however (Reynolds)

Progesterone facilitates the metabolic conversion of estrogens and hence lowers their rate of inactivation. Estrogen inactivation products help stimulate sex steroid secretion. The output of progesterone during the luteal phase of the menstrual cycle and about the thirty-eighth week of pregnancy is sufficient to reduce estrogen inactivation enough to remove the stimulus for sex steroid secretion. Stilbestrol stimulates progesterone secretion in human pregnancy as shown by its administration in a pregnant diabetic who had daily urinary pregnandiol determinations. A regimen of oral stilbestrol may prevent abortion, premature delivery pre-eclampsia eclampsia, or intrauterine death which may be due to progesterone deficiency (Smith *et al*)

Estrogens administered to pregnant women have an oxytocic effect which mounts as pregnancy advances, but no reaction takes place before the twenty-ninth week Uterine tonus and other characteristics of uterine contractility are intensified (Abarbanel, Effkemann, Murphy) Theoretically large doses of estrogens should induce labor (Reynolds) but practically attempts to use this oxytocic property clinically or experimentally to produce early abortion almost invariably fail. Labor is induced successfully only when the fetus is dead as in missed abortion or missed labor, and then usually in conjunction with other oxytocic agents (Abarbanel Jeffcoate Rieckhof Streit Voron *et al*)

Estrus inhibition in the mouse during gestation is dependent upon the presence of progesterone equal to the concentration obtained when a dose of 15 mgm is given daily This is probably due to the production of progesterone by the placenta, because the amount of estrogen required to produce vaginal cornification in the pregnant mouse is greater than the amount required in the non pregnant one (Robson) Progesterone in high dosage does not inhibit parturition in the rat (Bunde) but abortion after the spaying of pregnant mice is prevented by progesterone (Robson) Removal of the corpus luteum in monkeys after the first month of pregnancy (Hartman) or in women on the fifty-eighth day after the last period (Jones and Weil) or on the eighty third day after the first day of the last period (Duyven de Wit and Oppers) does not result in abortion. The termination of pregnancy in the rabbit is dependent upon the termination of the life cycle of the corpus luteum (Snyder) Gestation in the rabbit may be prolonged indefinitely by progesterone

injections. The fetuses usually die after the thirty sixth day (normal length of gestation 30 to 32 days) and are large and post mature (Koff and Davis, Heckel and Allen).

Injection of estrogen on the eleventh and later days of pseudopregnancy in the rabbit effectively prevents regression of the corpus luteum which normally occurs on the sixteenth or seventeenth day. Parturition in the rabbit is prevented, in the presence of the ovaries, by injection of estrogen in the latter part of pregnancy. The corpora lutea are maintained and their presence is the cause of continued delay of parturition. Doses of estrogen sufficient to delay labor always result in fetal death (Heckel and Allen). In the rabbit placental senescence may cause a declining estrogen level near term which correspondingly results in a decline in the corpus luteum and labor (Heckel and Allen see Mandel *et al*).

The administration of daily doses of progesterone, estrone, estradiol benzoate or triphenyl ethylene (a synthetic estrogen) to pregnant rabbits hypophysectomized on the twenty-eighth or twenty-ninth day after mating results in prolongation of gestation and delayed labor. Fetuses are often expelled from 4 to 6 days after the normal time. The delay in parturition is probably due to maintenance of the corpora lutea, which are large and normal in appearance. In the normal intact rabbit daily administration of estradiol benzoate from the twenty-ninth day on is less effective in prolonging pregnancy. This is presumably due to the fact that hypophysectomy removes the posterior lobe as well as the anterior and thus removes the source of oxytocin (Robson).

Hysterectomy in rats at any stage of the sex cycle does not produce luteal persistence, but hysterectomy in pregnant rats results in maintenance of the corpora lutea. Some factor in the uterus is antagonistic to the corpus luteum and this factor is negated in pregnancy probably by the placenta because without the placenta the corpus luteum regresses (Hechter *et al*). Hysterectomy in rabbits on the tenth or later days of pregnancy is followed by a considerable reduction in the size of the corpus luteum, maturation of follicles, and estrus. Injection of estrogen for 10 days, after hysterectomy on the fifteenth day, forestalls completely the expected involution of the corpus luteum (Greep).

Estrone and progesterone are rapidly inactivated in the mammalian organism, largely in the liver (Zondek). Diethylstilbestrol is less rapidly inactivated (Zondek and Sulman). Hexoestrol may be used to advantage in place of stilbestrol, particularly in 'phase' therapy (Crotty *et al* Ivy

and Gray). Both men and women are chemical hermaphrodites because both produce male and female sex hormones (Frank).

Chorionic gonadotropin blood concentrations fall after from 60 to 90 days of pregnancy in man to low constant levels (Allen *et al* Kurrok, A.M.A. Best and Taylor). Pre-eclampsia and eclampsia are characterized by unusual amounts of chorionic gonadotropin in the blood serum, preceding clinical signs by from 4 to 6 weeks. In hypertensive and nephritic toxemias normal levels are found. The discovery of high serum anterior pituitary-like hormone concentrations in the fifth, sixth or seventh month warrants suspicion of impending pre-eclampsia or premature delivery. A rise in gonadotropic potency after the fifth month of pregnancy is followed by a diminishing production of progesterone and estrogen. This may reflect a declining utilization of chorionic gonadotropin for the elaboration of estrogen and progesterone. Deficiency of these two steroids results in a deranged metabolism of both, ending in less complete conversion and more rapid destruction. Such a shift exists at the onset of labor if it is present before term it is accompanied by pre-eclampsia or premature delivery (Smith *et al*).

Cyotrin or chorionic gonadotropin may be produced by culture of placental tissue (Jones *et al* Gey *et al*). The cells responsible are probably the Langhans cells (Gey *et al* Mandel *et al*). Prolan is similar in man and monkey (Hartman). In the rabbit in which luteal activity is present in the ovary throughout pregnancy the gonadotropic hormone content of the pituitary gland increases throughout gestation reaching a maximum only a short time before parturition (Robson). Follicle-stimulating hormone and luteinizing hormone of the pituitary gland (FSH and LH) injected into pregnant rats during the latter part of pregnancy inhibit parturition. Heavily luteinized mulberry types of ovaries are produced by both extracts. The fetuses live beyond term and are often abnormally large. Unfractionated pituitary extract elicits the same results. Pregnant mare serum produces large follicles as well as corpora lutea and does not prolong gestation or inhibit parturition consistently (Bonde). Human pregnancy serum injected into pregnant rats inhibits parturition and causes early death and resorption of the fetuses. It stimulates the ovaries intensely with formation of additional corpora lutea, follicular cysts, and occasional hemorrhagic follicles. These effects are most probably caused by gonadotropins present in serum and disappear within 72 hours after delivery or abortion. The gonadotropins in human pregnancy serum appear to differ quanti-

tatively and perhaps qualitatively from those in pregnancy urine extracts and pituitary gland extracts (Rosenfeld *et al.* see Ivy and Gray)

Chorionic gonadotropin (antuitrin-S) injections prolong pregnancy in rabbits as much as 15 days after injection, by maintenance of the corpus luteum. Heavy doses of pituitrin at term fail to bring about parturition (Snyder). Injections of human pregnancy urine extract in female albino rats after implantation prolong pregnancy and result in the birth of frequently viable but post mature fetuses (King). If 18 day old albino rat fetuses are crushed and the tissue extracts injected into the abdominal cavities of pregnant albino rats, such implants continue to grow. Fetuses in pregnant rats so treated develop normally attain maximum size, and die. No labor ensues. "It would seem then, that these embryonic implants also secrete a chemical substance which is similar to the prolactin contained in pregnancy urine and as a result the presence of this tissue in the body affects the gestation period in the same manner as the injection of pregnancy prolactin" (Taylor)

Certain members of the German school have presented evidence to the effect that the uterine enervating or 'laming' factor in man is chorionic gonadotropin rather than progesterone. Presumably prolactin also maintains the corpus luteum and brings about elaboration of progesterone by the ovary. In addition, chorionic gonadotropin acts antagonistically to extract of the posterior lobe of the pituitary gland upon the isolated uterus of the castrated rabbit and upon the uterus *in situ* (Clauberg Tsutsulopulos). Prolactin may aid progesterin in neutralizing the influence of estrin upon the gravid uterus (Reynolds). No mention of this action of chorionic gonadotropin is made by other workers in the field (Ivy and Gray, Robson, Allen *et al.* Kurzrok Best and Taylor A.M.A.). Clauberg's group and Tsutsulopulos believe that the effect of the falling concentration of chorionic gonadotropin during pregnancy is readily overcome by rising estrogen. Uterine muscle sensitization to blood oxytocin possibly pituitrin, then increases until labor ensues. This theory is not inconsistent with the observations of Smith and Smith and their coworkers.

Either testosterone or desoxycorticosterone substitute for progesterone in many ways in the female organism. In menstruation the anterior hypophysis alone is not directly or actively responsible for the initiation of the menstrual flow but acts synergistically with the ovarian hormones. Menstrual bleeding follows the cessation of ovarian hormones, as after castration. Withdrawal of either estrogen progesterone after estrogen, or

testosterone results in uterine bleeding in castrate animals. Either testosterone or progesterone prevents the bleeding of estrogen withdrawal. The endometrium of ovariectomized monkeys after testosterone injections which follow estrogen is clearly proliferative. When estrogen is followed by progesterone and a secretory endometrium is formed, testosterone maintains this luteal endometrium (Engle, Bartelmez, Allen, Engle and Smith Hartman). Testosterone propionate delays parturition in pregnant rats while the young are externally masculinized (Hamilton and Wolfe). Doca (desoxycorticosterone acetate) in sufficiently large dosage prevents estrogen withdrawal bleeding in mature spayed monkeys and may even cause progestational changes (Zuckerman, Hartman). Doca maintains pregnancy in rats castrated and adrenalectomized. In view of the hypertrophy of the adrenal cortex in pregnancy, it is possible that the adrenal gland plays an important role in the course of gestation (Kehl *et al.*)

The adrenals fluctuate in size over a period of time corresponding to the estrous cycle. The changes are independent of either the anterior pituitary lobe or the gonads because they persist after removal of these glands. The adrenal cortices of spayed rats injected with daily threshold doses of estrone undergo cyclical alterations in size every 5 days. This is an inherent rhythm because it occurs even after removal of the pituitary gland (Bourne and Zuckerman). Uterine bleeding occurs in spayed monkeys treated with oestrogens only when the intensity of stimulation falls below a certain threshold level. A daily threshold dose of oestrogen thus periodically becomes insufficient for maintaining endometrial growth. The obvious inference is that rhythmical fluctuations occur in the sensitivity of the uterus to oestrogenic stimulation or that some factor other than the ovaries also exerts an influence on the cyclical changes that take place in the endometrium. One suggestion was that cyclical alterations in the activity of the adrenal cortex may lead to cyclical hydration and dehydration of the accessory reproductive organs and that such changes could determine variations in the responsiveness of the organs to oestrogenic stimulation. No proof exists for this theory.

Another possibility is that the adrenal cortex produces a subthreshold amount of oestrogenic hormone itself the amount produced varying cyclically becoming less or negligible, at times corresponding to uterine bleeding. The amount of effective oestrogen acting on the uterus of a spayed monkey injected daily with threshold doses of oestrogen would thus be the introduced

hormone supplemented by the oestrogen produced daily by the adrenals. Either source would by itself be insufficient to maintain the endometrium in a phase of growth, and bleeding would thus occur at times when the adrenal was not secreting any oestrogen. It is known that estrogen can be extracted from the adrenal cortex.

A third possibility is that the adrenal cortex cyclically produces, at times of intermenstrual bleeding, androgenic and/or progestational hormone, and that this endogenous hormone neutralizes the effect of the introduced oestrogen at those times. Alternatively such hormone may be produced continuously but in amounts which vary cyclically. Both of these hormones can be extracted from the adrenal cortex (Bourne and Zuckerman).

It is impossible to elicit artificial estrous cycles in spayed and adrenalectomized rats injected daily with constant doses of adrenal cortical hormone and estrone. Artificial threshold estrous cycles in spayed rats still occur after hypophysectomy. The extravarian factor which cyclically alters the estrogen threshold of the reproductive organs is probably the adrenal cortex (Zuckerman, Bourne and Zuckerman). Periodic uterine bleeding is evoked in spayed rhesus monkeys injected daily with a constant threshold dose of estrone. One of 5 animals thus treated has experienced an artificial threshold cycle after hypophysectomy (Zuckerman). Elicitation of artificial threshold estrous cycles is dependent upon the presence of the adrenals, and their influence upon the cyclical changes which occur is a direct one (Bourne and Zuckerman).

Similar findings have been reported in the production of cyclic vaginal changes in castrate rats, in which adrenalectomy immediately produces prolonged estrus (DiPaola). In parabiotic rat pairs consisting of a castrated male and a hypophysectomized female, the female exhibits continual estrus, with cornified cells in the vaginal smear. Testosterone or estrone injections into the male castrate partner of such a pair causes cyclic variations, in the vaginal smear from the hypophysectomized female as in a normal estrous cycle (Cutuly and Cutuly). In this connection normal cyclic ovarian changes have been observed recently in the vaginal smears from an artificial vaginal mucoea (Ayre).

A rhythmic rise and fall in estrone, estriol, and pregnandiol excretion prior to labor has been observed in the human. The controlling stimulus for this rhythm may be responsible for the onset of labor. However no connection exists between hormone analyses and the onset of labor because the latter may take place equally at the top or at

the bottom of a rhythmic rise and fall in hormone excretion (Hain).

The foregoing discussion of inherent physiologic rhythms, in which the adrenal apparently figures, brings to mind the older theories relating the rhythmicity of the menstrual cycle to the final onset of labor (Williams-Stander Stander DeLee, DeLee and Greenhill). 'Pregnancy is composed of a series of cycles.' Variations in the gestation periods of a species are such that the average gestation period may approximate a multiple of the (sexual) cycle (Snyder).

Numerous attempts have been made to determine the cause of the onset of labor by means of parabiosis in pregnant animals (see Schmidt). According to Sanderbruch and Heyde, if one rat of a parabiotic pair becomes pregnant the partner has tetanic seizures, suggestive of uremia, if it is either a male or a nonpregnant female. Whereas if the partner is a pregnant female it goes into labor whether at term or no and may abort or deliver. On the other hand, according to Kross, when both partners of parabiotic pairs are pregnant both proceed to term normally and labor in one partner does not affect the course of gestation in the other. Based on the experiments of the German workers, a theory of labor has been evolved in which an antigen-antibody reaction is assumed to occur as in anaphylactic shock. Fetal antigen reacting with maternal antibody forms an anaphylotoxin which causes uterine contractions. A gradual sensitization of the mother by fetal toxins takes place, with the onset of labor due to sudden intoxication by a large dose of fetal antigen. The anaphylotoxin is presumably the labor inducing body (Von der Heide). The intravenous injection of serum from women in labor into pregnant and parturient women elicits shocklike reactions or labor pains, according to von der Heide. However, the experiments of Kross on parabiosis and carefully controlled experiments on the pregnant guinea pig and pregnant women near term by Kolmer fail to substantiate the anaphylactic theory of labor.

The earlier reports of Levine and others, notably Hunt, on the relation of the Rh factor to repeated miscarriage or abortion should be mentioned in this connection because of the similarity of the Rh mechanism to the earlier anaphylactic theory. In a recent report, however, Hunt states that the Rh factor is not of great importance as a common cause of repeated miscarriage or abortion and becomes operative only in the latter half of pregnancy. Endocrine deficiencies of function are probably of more importance in habitual abortion than the Rh factor (Hunt).

Final summary and conclusions 'Emptying of the uterus is under hormonal control (Snyder) It is probable that progesterone and estrogen blood levels increase toward term. The decreased excretion preceding parturition reported by certain authors may represent increased utilization. Other authors, notably Browne *et al.*, Venning Hain, and Bachman, report no such drop in excretion levels. Hain remarks upon the individual variations prevalent in his series of cases.

The synergistic co-operation of the sex steroids causes increasing uterine activity during gestation. At optimal uterine distention with uterine muscle irritability at its highest point and aided by expanded calcium ionization blood concentration of the posterior pituitary secretion reaches threshold levels and brings about the onset of uterine labor contractions. Labor contractions are characterized by (1) appropriate magnitude, (2) rhythmicity (3) similarity (4) high tonus, (5) co-ordination and (6) effectiveness. Retraction of the uterine muscle, cervix, and lower uterine segment is inherent in the labor mechanism.

Likewise, it is probable that posterior pituitary secretion is continually present in the blood during pregnancy, but reaches uterine threshold concentration only at term. Labor ensues beyond the physiologic threshold of uterine muscle. If distention is close to the optimum, the blood progesterone and estrogen at a high level, the pituitary secretion at effective levels or any combination of these, the threshold may be exceeded before estimated chronological term. Both pitressin and pitocin may be normally present and physiologically active in total posterior pituitary secretion concentration in the blood so that artificial distinctions between them may be interesting experimentally but unimportant physiologically. It is possible that inherent physiologic rhythms (adrenal) provide a trigger mechanism after a certain multiple of the sex cycle has been exceeded. Theoretically then, it should be possible to initiate labor in the pregnant primate at will, using synthetic sex steroids and posterior pituitary extract to duplicate physiologic endocrine relationships. A clear cut and complete description of the precise physiology and etiology of the onset of labor in the primate may be expected in the future.

I would like to express my sincere gratitude to Dr Benjamin P. Watson without whose inspiration, assistance and co-operation this review could not have been written.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Marwell, J. H.: Chronic Proliferative Osteomyelitis of the Skull. *Ann Otol Rhinol* 1946 55 719

The author reports a series of cases of chronic proliferative osteomyelitis of the skull in which the tumor progressed to the point of simulating tumor formation or causing pressure symptoms. These he differentiates from osteoma or true bone neoplasm.

Chronic proliferative osteomyelitis is present in some degree in every case of chronic inflammation within pneumatized bone. This proliferative tendency of osteogenic tissue is dependent upon the conditions of stimulation. In early chronic proliferative osteomyelitis osteoid and pyogenic granulation tissue may be present later however, normal appearing bone trabeculae with only fibrosis of the marrow spaces may predominate. The diagnosis rests upon a combination of clinical, radiographic and histopathologic findings.

Thirteen case histories with roentgenograms are presented. Eight cases fitted the picture of chronic proliferative osteomyelitis in 6 of these the condition was apparently due to infection in 3 it was possibly related to trauma. In 6 cases the lesions were in or about the paranasal sinuses in 1 case, the mastoid, and in 1 the mandible. The remaining 5 cases were classified as fibro-osteoma. In the cases of fibro-osteoma, the presence of atypical bone trabeculae and atypical fibrous connective tissue in the marrow spaces reveals the true identity of the lesion. The treatment of chronic proliferative osteomyelitis consists in complete surgical removal of the newly formed bone.

Fernández, J. R., Corneillas, M. F. and Laconzo González, J. M.: Eosinophilic Granuloma of the Frontal Bone (Granuloma eosinofílico del frontal). *Radiología* B. Air 1946 9 34.

The third case of eosinophilic granuloma in the Argentine is here reported. Altogether there have been only about 30 cases reported for the entire world. A 14 year old boy with a frank history of allergic manifestations, consisting of rhinitis and pruritus of the right eye from eating peanuts suffered sudden intense pain in the right superciliary region, accompanied by edematous swelling of both eyelids. The pain was exaggerated by palpation. The condition was not changed by either the sulfas or by penicillin. Roentgenologically there was evident an osteolytic, nonreactive area of the right frontal bone, involving the orbit on that side about 3 cm. in diameter. The borders were sharply

133

delimited but irregular as though the result of a number of extensions of the process. Incision under local anesthesia transversally within the line of the eyebrow disclosed a soft, exquisitely painful mass which did not give to the curette any sensation of bony structure. Subsequent roentgen therapy brought about not only a cessation of the pains and a recession of the tumefaction and a swollen gland which had appeared at the angle of the jaw but roentgen examination 3 months later showed not only a reduction of the osteolytic area but in addition an osteogenic reaction which seemed to be progressively filling the pre-existent cavitation.

Histological examination disclosed the preponderance of eosinophilic histiocytes, both of adult forms with bilobulated nuclei and of young forms with spherical or oval nuclei. In places there were rare cells of large size, at times enormous with huge or bilobed nuclei and a finely syncytial chromatin characteristic of histiocytes. No evidence of the Hand-Schneider-Christian syndrome was noted (absence of exophthalmos, diabetes insipidus and lipodystrophy).

EYE

Sheppard, E. A. W. and Romejko, W. J.: Gonioscopy. *Am J Ophthalm* 1947 30 139

This article presents a simple technique of low magnification gonioscopy and shows the findings of examinations made by this method. It is primarily intended for the beginner because the low magnification makes it easier to orient the landmarks of the angle. The examination is made with the patient in the prone position and under pontocaine anesthesia. The gonioscope is inserted under the lid margin and the saline solution is then instilled between the lid and the cornea. Examination of the angle is made with an ordinary loop and with the illumination of an ophthalmoscope from which the head but not the condensing lens has been removed. In examining the normal eye the start is made at the pupillary border of the iris which is followed back to the "last roll of the iris." Usually a darker band can then be seen—the ciliary portion of the iris. Beyond this may be seen the fine strands of the pectinate ligament. The trabecular spaces are identified by a more or less pigmented dotted line. Above this is the corneal endothelium underlying the lamellae.

The authors list many conditions in addition to glaucoma in which gonioscopy is indicated the most common of these are the congenital anomalies the traumatic and inflammatory conditions the tumors the pseudotumors, and the cysts. Four traumatic cases were reported in which they found iris prolapse

traumatic ciliary dialysis peripheral anterior synchiae iritis deposits on the corneal endothelium, iris holes, and small foreign bodies in the angle. They also reported their findings in glaucoma and a leucomyoma of the iris, and noted that tremor of the iris is more magnified when looked at in the plane of the iris as in gonioscopy. ROBERT H. JOHNSON, M.D.

Schlaegel, T. F., Jr.: Histopathology of Atomic Bomb Casualties. *Am J Ophth.*, 1947 30 7

The author investigated the ocular histopathology of some Nagasaki atomic bomb casualties. He points out that disintegrating products of plutonium fission consist of fission fragments, neutrons, and beta particles, while the remainder are transformed into heat, gamma rays, and radiant energy such as ultraviolet visible, and infrared radiation.

The radiation sickness is similar to that which accompanies heavy total body irradiation. Its effect on the bone marrow results in aplastic anemia, fever, malaise, loss of appetite, bleeding gums, and hemorrhagic diarrhea. Irradiation of the entire body with 500 roentgens will kill. At Nagasaki there were 473 roentgens per sq. cm. at 1550 meters from the point where the bomb was dropped.

Sections of eyes were made of patients who had succumbed from the effects of the Nagasaki atomic bomb irradiation 1 month after the bombing.

Damage to the cornea and lens by radiation was the only direct injury observed. The cornea and lens were denuded but there was evidence of epithelial regeneration. It was indicated by the presence of small vacuoles in the superficial cortex and thickening of the posterior capsule that the lenses were probably developing regenerative cataracts. None of the characteristic histopathologic features of the effects of radiant energy on general body tissues was observed (giant and irregular nuclei, hyaline connective tissue and thick walled hyalinized blood vessels).

In addition to the histologic changes attributed to direct irradiation the following were attributed to the patient's systemic condition: serous exudation into and from the ciliary body; invasion of the eye by bacilli; septic choroiditis; nodular cellular infiltration of the retina; fibrin nets on the surface of the retina; and in 1 case, distention of all the ocular vessels by white chiefly mononuclear cells.

JOSEPH ZUCKERMAN, M.D.

Scholz, R. O., and Woods, A. C.: Relapsing and Chronic Ocular Lesions following Mustard Gas (Dichloroethyl Sulfide) Burns. *Arch. Ophth.*, Chic. 1947 37 39

The author reviews 136 cases of chronic and recurring mustard gas burns of the eyes (including 84 cases reported by Mann). The lesions were usually found to be bilateral, involving mostly the exposed palpebral aperture. There appeared to be slow but steady progress in serious visual loss in these cases.

No satisfactory treatment has been reported. The methods of treatment suggested included curettage

of the corneal tissue and tarsorrhaphy. A fair trial of corneal transplantation has not been completed. Contact lenses have proved useful in some cases.

HOWARD H. ROMANET, M.D.

Speweth, E. B.: The Marcus Gunn Phenomenon. *Am J Ophth.* 1947 30 43.

The Marcus Gunn phenomenon, congenital ptosis with an associated jaw-winking reflex, is found in approximately 1 per cent of all cases of congenital ptosis. The same condition in the acquired form of ptosis is known as the "pseudo-Gräfe syndrome." There is essentially an intermingling or misdirection of developing fibers of the third and fifth cranial nerves. There is a rather complete discussion of the various theories in the original article, but the conclusion is not very satisfactory.

In some of the cases there was a possibility that associated reflexes might have been the result of an afferent proprioceptive reflex pathway and a sympathetic efferent pathway. Other cases may have had brain stem internuclear pathologic, anatomic connections as the cause of the associated reflex. In still others the origin may have been in the supra-nuclear higher cerebral centers.

Surgical intervention was undertaken in several cases with a satisfactory result. An intracranial approach does not appear to be necessary.

WILLIAM A. MARKE, M.D.

Givner, J. Bruger M., and Lowenstein, O.: Exophthalmos and Associated Ocular Disturbances in Hyperthyroidism. *Arch. Ophth.*, Chic. 1947 37

Marine and his associates concluded that the sympathetic centers in the midbrain played a part in the production of exophthalmos, and Lowenstein has shown that pupillography can show evidence of central sympathetic disturbances. Therefore 22 patients with hyperthyroidism with and without exophthalmos were studied by this method. All but 1 showed a redilatation block which was interpreted as evidence of central sympathetic disturbance and therefore tended to confirm Marine's conclusion. Five patients without hyperthyroidism but with unilateral exophthalmos were examined in this manner and were found to have normal pupillary curves. More cases of this type must be studied before the value of pupillography in the diagnosis of unilateral exophthalmos can be established.

Since Mulvaney contends that the immediate cause of exophthalmos whether it be of the thyrotoxic or the thyrotoxic type resides in the extraocular and smooth muscles of the eyeball Tenon's capsule and the lid it was thought that the drugs used in the treatment of myasthenia gravis atony of the bladder and intestinal walls, and of muscular dystrophies may be of help in this condition. Consequently neostigmine bromide was tried in 5 patients with exophthalmos due to hyperthyroidism, but the results were unsatisfactory. Vitamin E and pyridoxine hydrochloride were also given without reduction of the

exophthalmos while ergotamine tartrate only temporarily narrowed the palpebral fissures. Oral administration of iodine reduced the exophthalmos in 3 patients and the authors noted 1 case in which the exophthalmos receded as pregnancy progressed. They reported a case of bilateral malignant exophthalmos with central scotomas and a bitemporal contraction. A Naffziger operation was done with removal of the upper part of the optic foramen on the right side but not on the left. The authors believed that this could have accounted for the recovery of the vision in the right eye and the almost complete loss of vision in the left eye.

ROGER H. JONKSON, M.D.

Goldsmith J.: A New Modification of the McReynolds Transplantation for Pterygium. *Arch Ophth Chlc.*, 1947 37 194.

The author suggests an explanation for the recurrence of the pterygia treated by the McReynolds transplantation technique and offers a new modification of that operation.

In the McReynolds transplantation operation a black silk suture is passed through the freed head of the pterygium and then through a subconjunctival tunnel to emerge from the conjunctiva. When the suture is tied the head of the pterygium is transplanted against this loose subconjunctival tissue. The author believes that this does not form a firm adhesion and that this adhesion may be disturbed or broken on removal of the black silk suture. He believes that if the retraction pull of the pterygium is sufficiently powerful it is not long before the head and neck of the retracted pterygium align themselves in the horizontal meridian to begin an invasion of the cornea again.

To prevent this retraction he has modified the McReynolds transplantation operation. The head of the pterygium is freed in the same manner the bulbar conjunctiva is undermined toward 6 o'clock in a narrow strip, and another incision through the conjunctiva and Tenon's capsule is made 5 mm. below the limbus. A double armed ovoid chromic surgical gut suture is introduced into the head of the pterygium from without inward and is pulled through the conjunctival tunnel and out through the lower incision. The needles are passed through the episcleral tissue and Tenon's capsule about 3 mm. apart. The head of the pterygium is then drawn through the tunnel and the suture firmly tied. The author believes that the pterygium head will then remain in place because of the attachment to a firmer tissue and because removal of the suture is unnecessary. He has had fewer recurrences of pterygia following this method.

ROGER H. JONKSON, M.D.

Grossmann, E. E.: The Stability of Penicillin in Ophthalmic Solutions. *Ak Ophth Chlc.*, 1947 37 167.

There has been considerable discrepancy in the reports on the stability of penicillin in solution or ointment form. An attempt was made to determine the

stability of penicillin in various vehicles both clinically and in the laboratory. White ointment was compared with isotonic solutions by means of a seeded agar plate and repeating every fourth day. There was extreme loss of potency in all samples after the fourteenth day. A cod liver oil suspension gave the same results, but an olive oil suspension retained 65 per cent of the potency of the penicillin after 21 days.

The stability of penicillin in blood plasma and human serum was studied and it was believed that these solutions gave the best results. The blood plasma appeared to give the best results and also to be more stable, with less turbidity and mold growth. It was noted that clinically good results could be obtained when the potency of the penicillin was considerably reduced as an extremely high concentration was not necessary in most cases when used locally in the eye. However, it should be used frequently that is, every hour or every 2 hours to maintain contact with the tissues.

WILLIAM A. MANN, M.D.

EAR

Fowler E. P.: Symposium on Noise, The Percent age of Capacity to Hear Speech and Related Disabilities. *Laryngoscope* 1947 57 103.

The author discusses the difficulty in measuring the binaural percentage loss of capacity to hear speech. He describes briefly his method which he suggested 5 years ago and which, he believes, should be accepted as standard for use in the Army Navy and Air Corps. He discusses the reasons why his method was not accepted by the Committee on Audiometers and Hearing Aids of the American Medical Association. He also discusses the method that was accepted and compares his own method with the other methods. He offers several changes that could be made in the existing method so that it would give results which correspond approximately to the results obtained by him. His discussions are quite long and complicated and anyone that is interested in this subject is advised to read the original article.

The author states that after obtaining a percent age of loss of capacity figure it was difficult to employ it in determining the disability suffered. This is true because no 2 people react the same to the same stimulus or to the same handicap or to its suddenness or rate or progression. In determining the handicap the prognosis of the hearing and the operative age would come into the picture. The handicap is less if the prognosis is favorable and if the patient can be helped by other means. Prognosis is a matter of clinical judgment and result of treatment. Operations are limited to favorable cases such as those with uncomplicated otosclerosis.

Hearing aids are useful in obstructive deafness even when complicated by severe neural lesions but not in total or near total deafness.

All these things being taken into consideration, it seems apparent that the degree of disability must be

determined in the courts using the percentage of hearing capacity as a basis for calculation, but only as a basis. The ability to overcome a handicap is often of greater importance than the handicap itself. Each case must be considered individually because the problem is never exactly the same in any 2 persons.

WILLIAM A. ARKROW, M.D.

Hoople, G. D., Wolfe, W. C., and Bregande, S. C.: Symposium on Noise. Unrecognized Battle Noise Trauma. *Laryngoscope*, 947-57. 5.

There have been many articles in the literature regarding the loss of hearing acuity following exposure to noise. From these studies it has been recognized that some individuals have a greater tolerance for noise than others. The authors became interested in the effects of battle noise on the ears of exposed soldiers who gave no complaint of deafness.

To determine whether or not there is any actual trauma to these soldiers exposed to noise, but without complaints, audiograms were made on 1,500 soldiers who had been in active combat but who had no complaint of hearing loss. It was impossible to determine the duration and degree of exposure to battle noise for each soldier. To obtain some comparable audiogram for a control series, 150 soldiers who were never exposed to combat were also examined. The composite audiogram of the 1,500 battle-exposed soldiers showed some loss throughout the entire range over the controls with the characteristic high tone loss beginning at the 2,000 level. A number of the soldiers stated that they had suffered a temporary hearing loss some time during the exposure but each maintained recovery of this loss by the time of the examination. The audiograms in a large percentage failed to show a correlation between the side of greater hearing loss and the side on which it was maintained that the explosion had occurred. A large number of the 1,500 soldiers complained of tinnitus, but no record was kept of this group and detailed questioning on symptoms was avoided so as to avoid any fixation in this regard. However when tinnitus was a complaint, audiometric loss of some significance was usually demonstrated. The records of 1,000 of the 1,500 exposed soldiers were studied in greater detail and divided into several categories.

In category 1 the soldiers were divided into two groups, those under 30 years of age and those 30 years of age or over. There were 20 in the second group and 790 in the first group. The difference in the audiometric readings in these two groups was hardly significant and any difference could be laid to the difference in age rather than to any greater susceptibility of the soldiers more than 30 years of age. There seemed to be sharp evidence that a soldier over 30 is liable to greater audiometric injury to noise than a soldier under that age.

In category 2 the 1,000 soldiers were divided into two groups and studied by means of a Seigle's speculum. The two groups were those showing normal motility of the ear drum and those with restricted motion of the ear drum. The latter of the two groups

gave some evidence of previous inflammatory lesions in the middle ear which had resulted in some adhesions. Roughly about 21 per cent showed limitation in motion of the drum or malleus. There was an appreciable, but not significant, difference between the two groups. It could not be determined whether or not middle ears with evidence of previous disease were more susceptible to noise trauma. One can only say that diseased ears were as susceptible as normal ears.

In category 3 the soldiers were divided into two groups, those exposed to battle before October 1, 1944 and those exposed after that date. That was done because there was greater concentration of gunfire in the earlier stages. There was no appreciable difference seen between the two groups, probably because the cochlear damage sustained in battle is the result of very intense noise of short duration rather than prolonged noise of less intensity.

A fourth category separated the soldiers who had fought with the infantry from those in the armored divisions. Comparison of these two groups showed that those in the infantry showed a slightly greater hearing loss than those in the armored divisions. It is believed that this difference may be due to the fact that those in the armored divisions had their ears protected somewhat by the wearing of earphones and football type of helmets.

Category 5 divided the 1,000 soldiers into another two groups, the first including those whose hearings in both ears was better than 30 decibels in each of the ten frequencies tested, and the second group including those who had 30 or more decibels loss in any one of the ten frequencies in either ear. The first group in this category showed an audiometric curve which approximated the curve of the so-called normal. Thus, in a rough way this separated the normals from the acoustically abnormal. In other words, it shows that 30 per cent of an average group of soldiers not complaining of hearing loss had as much as a 30 decibel loss in at least one frequency in their audiometric chart. In group 2 of this last category 70 per cent of the exposed soldiers showed a like deficiency. Thus, among the soldiers in a battle exposed group there were 40 per cent more who showed this audiometric deficiency than in the average nonexposed group. Thus, in a rough manner point out that a very appreciable number of soldiers who have been exposed to battle noise have a recordable degree of acoustic trauma. It is impossible without a previous audiogram to state fairly whether any given soldier is or is not the victim of acoustic trauma from the battle noise.

Because of the fact that 30 per cent of the so-called normal will have some hearing decrease, a more careful hearing test should be done on each individual on induction into the army. This would help to decide whether or not these particular soldiers have suffered any hearing injury during their army career as the audiograms taken on induction and discharge can be compared. It is also unknown whether or not the individuals in the different groups will have any effect

from the injury in 5 to 40 years hence. It is only an examination in the future of this series of cases if possible that could tell that fact.

WILLIAM A. ABRON M.D.

Sensory E. T : Symposium on Noise. A Study of Cases of Acoustic Trauma from a Comparison of Patterns of Deafness. *Laryngoscope* 1947 57 142.

In medicolegal cases it is frequently difficult for the otolaryngologist to differentiate between true and fancied acoustic injuries. There is often disagreement between the experts and the writer believes that if certain facts would be generally recognized, history, and comparison of audiograms of deafness produced by disease with those of deafness due to trauma will prevent much confusion. The author discusses deafness caused by skull fractures, concussion from blows on the head, concussion from blasts or excessive noise, concussion from the telephone receiver causing deafness and direct penetrating injuries.

In all of these cases, any deafness is immediate and in most instances the hearing improves following the injury while in some it may remain the same and in a few becomes worse, particularly if ear infection follows the accident. The writer states that if the plaintiff claims that his deafness was first noticed months after the trauma, he has no proper claim.

Along with the deafness is usually tinnitus, vertigo, and disturbances of equilibrium. The tinnitus may persist but the vertigo usually disappears although at times it may recur at a later date and be more disabling than any actual deafness that may remain.

In traumatic injuries to the ear drum much hearing impairment rarely occurs but it is usually worse if the ear drum is not ruptured. However if infection follows a ruptured ear drum, the hearing loss may be severe. Pain, tinnitus, and vertigo, but usually only slight deafness follows the accident and except for the tinnitus the symptoms disappear quickly. If the patient is not seen immediately after the accident and infection follows it may be difficult to state whether or not his difficulty was due to trauma or to a simple middle ear infection.

The author has seen no cases of ear trauma following the use of the telephone but he mentions many cases that have been reported in the literature. The writer has had no cases of blast deafness but he mentions several cases reported.

He states that it is difficult at times to differentiate between occupational deafness and slowly progressive deafness which is frequently encountered in older people. He mentions some conclusions that have been arrived at by Bunch concerning occupational deafness. As a rule the hearing loss is in high tones and occurs in the hearing range in the same area of the spectrum of the noise to which the ear was subjected. He discusses briefly several of the laws in the different States covering this problem.

He states that the only way that both the employer and employee can be protected is by having pre-employment audiograms done on those employees who are subjected to industrial noises and to reduce the noise of industry.

In deafness due to injuries to the head, it is frequently difficult to determine if or not the deafness was due to the injury. There has been much controversy throughout the years and the proper use of the x rays and audiometer will help to solve the problem. The writer believes that in the cases with a history of violent symptoms of labyrinthian disturbance, lessened response to vestibular tests and an audiogram showing perceptive hearing loss, the pattern of which does not conform to deafness caused by disease, indicate that the hearing loss has been caused by the accident. At times in certain cases of deafness no definite statement can be made unless a careful history eliminates exposure to noise.

In deafness following head injury there is usually a sudden drop in the high tones while perception of deafness caused by disease will cause a slowly decreasing curve in the high tones.

The writer includes a number of short case reports and shows numerous audiograms to illustrate the different types of deafness which may follow trauma.

WILLIAM A. ABRON M.D.

Simonton, K. M : Study of Acute Otitis Externa, with Special Reference to Secondary Myringitis, and Otitis Media. *Am Surg* 1947 13 136.

The present study is based on observations which were made in a period of 2 years in military hospitals in New Guinea and the Philippine Islands. Patients observed include both outpatients and hospital patients. In addition a review was made of the records in 341 consecutive cases in which the diagnosis of otitis externa was made. The patients were observed in New Guinea from May to September inclusive, which is the rainy season. At that time the incidence and severity of otitis externa is greater than during the relatively dry season.

From this study the following points seem worthy of emphasis.

Otitis externa is of frequent occurrence in the tropical islands of the Southwest Pacific probably because of the extremely high humidity. The condition is of military significance because of time lost from duty because of this disease.

Degeneration of cerumen in the external auditory canal is responsible for the primary infection in most cases.

Inflammation of the tympanic membrane occurs as a result of irritation from secretions in the external auditory canal.

Perforation of the tympanic membrane and infection of the tympanic cavity result from formation of ulcer on the tympanic membrane.

Thorough cleansing is the most valuable therapeutic procedure. Ointments and strong drugs are poorly tolerated. Intravenous administration of foreign protein together with the administration of one

of the sulfonamides or penicillin produced striking improvement in cases of severe otitis externa. No one regimen or drug has been used which is definitely superior to others.

Wells, F. L.: Superior Petrosal and Cavernous Sinus Thrombosis and Basal Petrositis Observed as a Complication of Destructive Labyrinthitis with Facial Paralysis. *Arch. Otolaryng. Chic.* 947 45 90.

The author describes one of the most interesting otological cases he encountered during nearly two decades of service at the Massachusetts Eye and Ear Infirmary Boston. He discusses at some length the management of paralysis of the left side of the face complicated by an acute exacerbation of chronic suppurative otitis media on the left side with mastoiditis and destructive labyrinthitis; the management of superior petrosal and cavernous sinus thrombophlebitis and supracochlear basal petrositis with destructive labyrinthitis and the management of meningitis as a complication of the thrombophlebitis and petrositis. The facts presented may provide objective experience for other otologists with similar difficult decisions. NOAH D. FABRICANT M.D.

NOSE AND SINUSES

Eisenstadt, L. W.: Management of Septal Deformities in Rhinoplastic Correction. *Arch. Otolaryng. Chic.* 947 45 77.

The author discusses the management of septal deformities in conjunction with rhinoplasty. A submucous resection either partial or complete, is advocated for about 80 per cent of cases in which a nasal plastic procedure is done. A submucous resection and rhinoplasty offer marked improvement and even cures in cases of mild or moderate vasomotor rhinitis. It is easier and more economical to perform submucous resection in conjunction with rhinoplasty than to do each at separate operations. If a curving in of the dorsal septum results from undue traumatism it should be immediately corrected by suturing the fractured ends together suturing the upper lateral cartilages together over the dorsum of the septum instilling a piece or pieces of resected cartilage or bone into the dorsum or by "pinning" the septum in place. It is always advisable to suture the submucous incision to prevent adhesions when septal resection is performed in conjunction with rhinoplasty. NOAH D. FABRICANT M.D.

Gatewood, W. L.: Improved Surgical Technique Based on Modifications of Jansen-Ritter (Lynch) and Caldwell-Luc Procedures for Chronic Sinusitis. *Arch. Otolaryng. Chic.* 947 45 4.

A striking impression gained from a broad survey of present-day literature pertaining to the management of chronic sinus disease indicates that efficacy is materially lessened by a lack of clear-cut agreement and mutual understanding among many of

those who are considered authoritative on this subject. While there can be no question as to the value of medical treatment as an adjunct to surgical treatment in chronic disease of the sinuses, certain of the older practices such as nasal suction, the use of tampons and irrigation can serve only as palliative measures. At the same time many who have become enthusiastic on the subject of nonsurgical treatment have clouded the issue by advocating pseudo-surgical practices, including physical and chemical therapy, that are of questionable value and claiming results that cannot be verified by clinical evidence.

This has been far from helpful to the somewhat isolated practitioners of medicine or surgery who frequently have the opportunity to advise or treat such patients. A natural corollary is a disastrous confusion in the minds of many which fosters delay and a fatalistic acceptance of what they have come to regard as the inevitable.

The sole rationale of procedure is placed firmly on an essential scholarship in the medical sciences of anatomy physiology and pathology. Too much emphasis cannot be placed on the great importance of studying anatomy on the cadaver thoroughly as a prerequisite to operating on the living subject. This experience is gained under proper supervision. A textbook knowledge of anatomy is important, but practical study of the subject in the anatomical laboratory is essential to a thorough understanding of surgical anatomy which is so necessary at the operating table.

A thorough clinical anatomy of the accessory nasal sinuses the nasal cavity and the septum is presented, along with 18 figures illustrating the technique and surgical procedure. With this technique the author accomplished complete removal of pathologic tissue the conservation of operative time, and the reduction of trauma of healthy tissues to a minimum. The function of the nose is left undisturbed, and intra-nasal inspection at any subsequent time encounters no gross evidence that operative procedures have been undertaken.

With the patient who has a history of long-standing chronic sinus disease and whose sinuses contain thickened membranes with irreversible degenerative changes not responding to nonsurgical treatment the only sound surgical procedure is the thorough removal of the membranes and any diseased bone that may exist.

Postoperative healing is obtained by the formation of a dense layer of fibrous connective tissue which becomes epithelialized as the mucous membrane of the nose grows into the sinus cavities.

Diplopia is seldom encountered, and in the rare cases in which it occurs, is only transitory. As to the facial appearance, esthetically speaking the incisional wound is not recognizable.

In subjects with extremely large frontal sinuses showing multifocal recesses and extending laterally to the zygomatic bone, an incision of greater extent will be required in the manner of the Killian procedure. JOHN F. DILLON, M.D.

Burnam C. F.: General Factors in Irradiation Therapy *Ann Otol Rhinol* 1946, 55: 764.

Burnam points out that irradiation can be used in advantage in a great many otolaryngologic and ophthalmologic conditions that it is simply a method of treatment, just as is a surgical procedure or the use of bactericidal and bacteriostatic drugs. Specialists in ophthalmology and otolaryngology should master the principles of ray therapy and either carry out the treatments themselves or have them carried out in the way that is likely to produce the best results. Initially practically all patients suffering from new growths and from various infections come to the specialist who is in a position to study and assess the value of therapeutic procedures. So far as beta ray applicators are concerned, their use is simple. With x rays and implantation, co-operation between a competent radiologist and a specialist is perhaps the best method of procedure.

NOAH D. FABRICANT, M.D.

MOUTH

Goodsell J. O. and Others: Fractures Involving the Mandibular Condyle *J Oral Surg* 1947, 5: 45.

This article deals with fractures of the mandible at a site above the mandibular notch and severing the articular head of the condyle from the ascending ramus. One hundred and twenty cases are reviewed by the Chalmers J. Lyons Club whose members made an excellent follow up study.

Although structurally the neck of the condylar process appears to be the point most vulnerable to mandibular fracture, clinical statistics reveal that only 8 per cent of mandibular fractures occur at this site. The apparent increase in the number of these fractures recently may be attributed to the growth of a hazardous mechanized environment.

The anatomy of the mandible is discussed thoroughly and its clinical application pointed out.

The fractures were classified as follows:

Displacement fractures (condylar head remains within the limits of the temporomandibular joint)

- Anterior
- Posterior
- Medial
- Lateral

Dislocation fractures (condylar head leaves the limits of the temporomandibular joint)

- Anterior
- Posterior
- Medial
- Lateral

The clinical signs of fracture of the mandibular condyle may be scarcely perceptible, and symptoms may be negligible or absent. Frequently roentgenographic findings are the first to disclose a condylar fracture. All degrees of signs and symptoms may be present and it is surprising to find that there is no constant correlation between the extent of fragment displacement and magnitude of clinical deformity.

In spite of marked displacement evidenced in the roentgenogram, there may be no occlusal imbalance or significant functional disturbance. Fractures with minimal displacement are usually unaccompanied by great deformity or functional disturbance. Clinically upon digital palpation of the anterior wall of the external auditory meatus an absence of normal excursion of the condylar head will be found on the side of fracture. Palpation at the preauricular fracture site may reveal crepitus during function. Gross displacement of the condylar head may be disclosed by palpation if it is not marked by edema. Preauricular pain may be manifest with an increase in tenderness during excursions of the mandible. In direct fractures, contusions, swelling and other obvious traumatic signs are found.

Disturbances in the occlusal relationship of the teeth is commonly present. The degree of trismus varies greatly.

The aims of treatment are restoration of normal function with correct occlusion, or interarch relations if the patient is edentulous and the elimination of the associated deformity. Reduction is accomplished by open or closed methods. Closed reduction is the preferred method, and when general anesthesia is used the best reduction is possible. Various types of intermaxillary fixation are employed and 3 weeks of immobilization are usually sufficient.

Although condylar fractures disturb the complex structure of the temporomandibular joint and theoretically would seem to raise havoc with jaw function the clinical studies of a large group show complete functional readjustment in nearly every case.

The aim of treatment is not the x ray evidence of fragment realignment in correct anatomic position as these fractures do well and attain satisfactory function without accurate realignment.

Surgical methods have few indications and many hazards. The handicaps and complexity of surgical intervention are discouraging. Open procedures introduce additional trauma and invite infection and dislocational complications.

Ankylosis was a rare complication.

In patients not skeletally mature no disturbances of epiphyseal growth occurred.

EDWARD R. DOKOSCHUX, M.D.

Provecho, M. C.: The Surgical Treatment of Epitheliomas of the Face and Buccal Cavity with Especial Reference to the Immediate Plastic Repair (*El tratamiento quirúrgico de los epitelomas de cara y cavidad bucal, con especial referencia a la reparación plástica inmediata*) *Rev espal cir.*, 1945: 453.

Metastases in cancer of the face occur in 1 per cent of the cases. Secondary growth may be found in distant organs. The mortality rate is relatively high and should be reduced because the location of the tumor is typical, easily accessible, and diagnostically simple.

Treatment on the other hand results in much pain and mutilation. This is brought about partly

by the application of therapeutic agents which are to be condemned. The application of nitrates, various caustic pastes, or carbon dioxide often results in unnecessary disfigurement and inadequate treatment. The collaboration of surgeon and radiologist is often disappointing because the treatment falls into a vicious circle. The radiologist has no opportunity to treat the surgical case when indicated and the surgical case is submitted to radium or x rays when neither is of value. The principal objection to surgery is that often a considerable amount of tissue has to be sacrificed, and much plastic repair has to follow if deformity is to be avoided.

The author presents the indications and methods of treatment to be employed in the various epitheliomas of the face and mouth. This therapy is based on experiences gained in the surgical section of the National Institute for Cancer in Madrid.

The principal indications for surgery are that the tumor is of large size, near the bone or cartilage, radioresistant, recurrent or precancerous in type. When metastasis has occurred to the lymphatics these should be removed at the time of operation.

Surgery is contraindicated when the lesion is reasonably incurable, the general condition of the patient is bad, or infiltration has extended to the deeper glands.

Immediate plastic repair with various types of grafts is emphasized. Diathermy coagulation and extirpation is resorted to when indicated particularly in the recurrent type of tumor and extension of growth into the craniofacial bones requires special consideration according to the bones involved.

STEPHEN A. ZUCKMAN, M.D.

NECK

Sweet, R. II: Pulsion Diverticulum of the Pharyngoesophageal Junction: Technique of the One-stage Operation. *Ann. Surg.* 947 254

The author reviews the technical details of the earlier one-stage method for excision of diverticula

of the pharyngoesophageal junction, and suggests the reasons for the difficulties which were encountered.

Early attempts to perform the entire operation in one stage led to discouragement as a result of the frequent occurrence of deep cervical or mediastinal infection and the development of fistulas. To avoid these difficulties the author adopted the two-stage technique which minimized the complications to a large extent, but did not prevent the occurrence of the occasional fistula. Though this represented a definite improvement he believes that by observing certain refinements of technique described in the article, and taking advantage of the protection against infection which results from the prophylactic use of penicillin and sulfadiazine, it is possible once more to resume the use of a one-stage procedure with its resulting advantages and the saving of approximately 2 weeks' hospitalization.

The author describes the principles of technique, viz. a minimum of handling and trauma, accurate dissection, proper care in placing sutures, such as (1) avoidance of damage to cut-edge, (2) securing an accurate layer-by-layer approximation of the edges, (3) insurance of an adequate blood supply and avoidance of the use of a drain or lying tubes in the esophagus. The preliminary preoperative preparation with penicillin and sulfadiazine is given, followed by a description of the actual technique of operation, the use of intratracheal anesthesia (ether) the method of approach, and the manner of removal of the diverticulum. The author avoids the old idea of tying the diverticulum at its base and inverting the stump into the wall of the esophagus, by cutting it at its base and the resulting defect is closed in two layers with interrupted fine silk sutures, thereby substituting a neatly closed vertical incision for the bunched-up wall at the site of inversion of the tied-off stump. The postoperative management is then described.

The average hospital stay in 5 such cases was 11 days.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Mount L. A.: Premature Closure of Sutures of the Cranial Vault—A Plea for Early Recognition and Early Operation *A. J. Surg.* 1947 47 370.

Premature closure of any one or more of the sutures of the cranial vault results in marked abnormality in the shape of the skull and hence of the brain. Early closure of the sagittal suture results in a long narrow skull closure of the coronal sutures in a broad short and occasionally high skull and closure of both coronal and sagittal sutures in a high skull. Illustrations of each of the various types are presented.

Surgical treatment is discussed and the author relates views briefly the operative techniques of Sharpey, Cushing, Bauer, Keegan, Faber and Towne and others. He contends that since the symptoms and signs result from closure of the suture opening of the closed suture should be the best treatment. Accordingly a strip of bone from 6 to 10 mm. in diameter was removed at the suture which opened it in its entirety. No significant bleeding from the sagittal sinus was encountered. The dura separated readily from the bone beneath the closed suture.

Six case reports are described, 4 involving the sagittal suture and 2 the coronal. The youngest patient operated upon was 3 months old and the oldest 24 years old. The best results were obtained in the patients in whom the operation was performed earliest. None of the patients had signs of increased intracranial pressure either before operation or subsequently. Two who were retarded mentally were still retarded 22 months and 4 months, respectively after the operation. In 3 of the patients it appeared that a new suture line with interdigitations developed. It appeared from roentgen examination that the suture was normal and thus far it has remained open in both cases for 18 months after operation. In 2 other cases a thin layer of bone representing only the outer table had bridged the defect. Early recognition of closure of the suture and early operation is necessary in order to obtain the best results.

HOWARD H. LANKER, M.D.

Amyot R.: A Contribution to the Study of Lipoma of the Corpus Callosum (Contribution à l'étude du lipome du corps calleux) *Union méd. Canada* 1946 75 1391.

The author presents a case of lipoma of the corpus callosum, discussing its diagnostic signs and symptoms and differentiates it from agenesis of the corpus callosum and septum pellucidum cysts.

The patient had severe headaches since childhood and convulsive seizures but no other localizing symptoms. The diagnosis was made by means of roentgenograms of the skull and pneumocephal

ographic studies which showed dilated anterior horns and lateral ventricles separated by a round mass with a calcified capsule. Removal of the tumor produced a right hemiplegia and marked distrust of the frontal lobe.

The author advises against operation as the surgical sequelae were worse than the preoperative symptoms of this benign congenital neoplasm.

GEORGE PERRET, M.D.

Gregori A.: Meningioma in the Mastoid (Meningioma nella mastoide) *Radiol. med., Milano* 1946 33 395.

The author presents a case of meningioma in the mastoid and discusses it from the point of view of roentgenological differentiation. He finds no reports of such cases in the radiological literature.

The case was that of a male 42 years old who 2 months after an attack of otitis media which cleared up in 10 days suffered retroauricular pain followed by the appearance of a tumefaction in the right mastoid region. The swelling was elastic but not fluctuating and disappeared completely after 10 hours. The same phenomenon occurred 10 days later and this time the tumefaction persisted 18 hours. The patient entered the hospital and roentgen ray studies revealed the right mastoid region to be occupied by a transparent area, round, sharply outlined about 2 cm. in diameter with millet seed sized bony transparent areas scattered in a cloudy center. The apex of the bone was normal. In the differential roentgen ray diagnosis the author considers 1. Normal mastoids with single transparent cavities as reported by Steurer. The author's case differed because the lacuna was large and the polygonal characteristics of the mastoid cells had disappeared completely.

2. Acute mastoid with abscess formation. Here the lacuna may be as large as in the author's case but the outline is cloudy and there may be rarefaction of bone as well as small sequestra.

3. Cholesteatoma secondary to chronic otitis media. Against this diagnosis were the absence of eburnation of the mastoid, the location of the bony defect which normally occurs in the antrum and in the attic, the normal appearance of the tympanic membrane and the normal acoustic studies discarding the possibility of a tubercular process, actinomycosis or gumma.

4. The anamnesis and serological studies discarding the possibility of a tubercular process, actinomycosis or gumma.

5. Cyst. This is preceded by otitis media early in life, followed by alteration or destruction of the anatomical constituents of the ear and loss of hearing.

6. Neoplasm primary or secondary. Steurer (Henke Loharsch) Mayer have described such cases but the lacuna is irregular and not sharply outlined.

7. Primary cholesteatoma of the mastoid due to the presence of embryonal cells in the temporal bone, described by Amersbach as epidural cholesteatoma or mucocoele of the mastoid cells. Roentgenologically this is very much similar to the condition in the author's case but the clinical picture is very different.

8. Benign tumor. The author's case might have been a benign tumor but he was unable to explain the alteration of the mastoid as a consequence of such tumor. Surgical intervention revealed a large cavity 3 mm. from the bony cortex, filled with gray tissue and waterlike fluid. This neoplastic mass which was attached to the dura of the middle cranial fossa was removed and histological examination revealed it to be connective tissue. A tumor of this type was named "meningioma" by Cushing. Meningiomas originate from endothelial arachnoid cells enclosed in the dura mater are somewhat prevalent along the sinuses, and communicate with the dura of some of the cranial nerves. The author's case could be classified an endothelioma, as this often occurs in the petrous bone and clinically gives the symptoms and signs of an endocranial tumor.

JOSEPH M. A. PARR, M.D.

Kubanyi A.: The Treatment of Trigeminal Neuralgia by Intracranial Coagulation of the Gasserian Ganglion (*Sur le traitement de la névralgie du nerf trijumeau par l'électro-coagulation intracrânienne du ganglion de Gasser*). *Lyon chir.* 1940, 4, 68.

The author opens with the statement that when comparisons are made of the efficacy of various methods of treatment for any one disease, those treatments longest in use usually show up in a more favorable light than the newer treatments. He believes, however, that the relatively new operation of coagulation of the gasserian ganglion for the treatment of trigeminal neuralgia, first propounded by Kirschner in 1931 merits wider consideration and use. His experience with 30 patients so treated would seem a wide enough one for the expression of an opinion.

A review of the various methods of treatment of trigeminal neuralgia shows that operative difficulties, recurrence of symptoms and untoward side effects may occur no matter what form of treatment is used. The alcoholic injection of the terminal branches of the nerves or of the lower two divisions at their foramina of exit, the early operation of ganglion extirpation by Frazer the common operation of neurotomy of the root proximal to the ganglion either by the subtemporal route or by the newer and more difficult suboccipital approach, and the latest method, advanced by Sjöqvist in 1938 of performing tractotomy on the descending sensory pathways of the trigeminal nerve within the lower brain stem, are all reviewed briefly by the author.

The accurate coagulation destruction of the gasserian ganglion presupposes the accurate localization of the ganglion before operation. The author has

carefully worked out the anatomical co-ordinates for the passage of the insulated trocar with its central electrode, and the operation, done under general intravenous anesthesia is always performed under roentgenographic control in the department of roentgenology. The instrument is passed through the foramen ovale the ganglion lying at a distance of 19 mm. from the foramen. Repeated coagulation may be necessary to obtain complete relief but while pain is completely abolished, normal sensation may begin to return as early as 3 weeks after coagulation.

Among the author's 301 patients 217 were considered cured. Coagulation was performed twice in 75 patients, 3 times in 85 patients, and 4 times in 12 patients. Postcoagulation paresthesias occurred, apparently in much the same way as they occasionally occur after operative resection of the posterior root. An occasional hemiplegia resulted, as well as some occasional damage to the extraocular muscles, and the keratitis of anesthesia. JOHN MARROT, M.D.

Bajer A.: Contribution to the Problem of Post-operative Anesthesia Dolorosa of the Trigeminal Nerve (*Příspěvek k problému pooperační anesthésie dolorosa trojklaného nervu*). *Lék. listy* 1940, 577.

A middle aged woman, who experienced a severe menopause and was now suffering from high blood pressure (220 mm. Hg) developed a typical neuralgia of the trigeminal nerve at 60 years of age and was operated upon by Kirschner's coagulation of the gasserian ganglion on a different occasion without permanent relief. She was then subjected to a juxtapuncture radiotomy with interruption, through the occipital route of the lower and outer two-thirds of the sensory root of the trigeminal nerve on the left side. There was immediately a loss of sensation over the region supplied by the first and second branches of the trigeminal nerve with lowered sensitivity to touch and lack of the sensations for heat, cold, and pain on that side. The corneal reflex was absent and the patient complained of seeing double and of spasms of the musculature of the left side of the face. The blood pressure dropped to 135/70 mm. Hg.

At re-examination 2 months later there was present a mild enophthalmos and narrowing of the ocular cleft (Horner's syndrome) on the left side, a lowered corneal reflex, hypotonia of the left masticatory muscle group and mild deflection of the tongue to the left side. The left palatal arch was lowered and narrowed there was lowered sensitivity over the left half of the mouth cavity larynx, and anterior two-thirds of the tongue, and a lowered pharyngeal reflex on that side. Over the area supplied by the left trigeminal nerve there has persisted a lowered sensation to touch and nonsensitivity for heat, cold, and pain; however, pressure over this area produced a burning pain which was most pronounced over the left symphysis region and pressure over the sympathetic plexus of the left carotid produced burning pains over the left half of the face which however

persisted for but a short time. At the same time there occurred a marked dilatation of the left pupil. There was also increased sweating over the left half of the face accompanied by an abnormal flushing.

The author recognized these manifestations as an irritative hyperpathia and a sympathalgia, or neuralgia, of the sympathetic nerves and ganglia of the left side of the neck and head, and maintained that they correspond to the *anesthesia dolorosa* as described by Olivecrona, that they are not related to a recurrence of the trigeminal neuralgia, and that they do not require further surgical interference. The irritative hyperpathy could not be influenced by medication but did not trouble the patient very much. The sympathalgia was controlled by giving extractum *fungi secalis* (o i) with luminal (o oz).

JOHN W. BRENNAN, M.D.

SPINAL CORD AND ITS COVERINGS

Begg, A. C., Falconer, M. A., and McGeorge, M.: Myelography in Lumbar Intervertebral Disc Lesions. *Brit. J. Surg.* 1946 34 141.

The authors present results from 86 myelograms done for the investigation of low back pain and sciatica in an attempt to clarify the controversial issues raised in the past regarding the value of this procedure.

Four separate groups of disc lesions are described:

1. Projections
2. Intermittent prolapses: the intervertebral protrusion which occurs only when the vertebrae are subjected to certain strains (also known as the *concealed disc* of Dandy).
3. Extrusions: the condition present following rupture of the annulus fibrosus with escape of the nuclear material into the spinal canal.
4. Scarred discs: over a period of years the opposing surfaces of vertebral bodies may become sclerotic with bony lipping, decrease in the size of the disc space, and subsequent adhesions of the theca and extrathecal nerve roots to the back of the discs without any actual soft tissue projection.

Although their method of examination is essentially the same as that used by other investigators, the authors have employed certain distinct features which need enumeration. The needle is inserted while the patient is horizontal and 3 c.c. of contrast medium (lipiodol or pantopaque) are injected. The patient stands on a vertical tilt table and the table is then tilted downward slowly. Occasionally it may be necessary to turn the patient obliquely to obtain better filling of the root pouches. As the contrast medium straddles each disc space anteroposterior spot films are taken and the tilt angle noted. After the lumbar interspaces have been inspected the tilt is reversed and the medium observed as it flows backward. Prone lateral views of the two lower lumbar interspaces are taken routinely; these have proved of help in diagnosing certain disc lesions. Oblique views rarely reveal information which cannot be ascertained from the lateral and anteroposterior views.

A recent innovation is used in demonstrating the "intermittent prolapse." This consists of having the patient hyperextend the spine by raising his head and shoulders. This maneuver has shown lesions which were not apparent by the usual method of examination. No harmful effects have been observed from either the injection of the contrast medium or allowing the material to remain within the thecal cavity. Although lipiodol was usually aspirated at the time of operation, pantopaque was allowed to remain *in situ*. Follow up roentgenological examinations have shown that this substance is slowly absorbed at a rate of approximately two-thirds of its volume in a year.

The arrangements of the individual nerve roots composing the cauda equina have been found to conform to two general pattern types. In one the nerve roots are separated from each other so that those about to pass from the thecal cavity are lateral while the remainder lie medially. In the other variety the nerve roots lie in two large bundles, one on each side of the midline with a wide free space between. The individual members are arranged so that the cephalic roots are anterior. The anterior wall of the theca is closely applied to the posterior surfaces of the posterior longitudinal ligament except where the lumbosacral angle is more acute than usual (as at the fifth lumbar disc) and a few millimeters of fatty tissue are interposed. This explains why disc lesions at the fourth and higher lumbar spaces affect the myelograms more obviously than prolapses at the fifth lumbar interval.

Myelographic abnormalities usually affect the thecal column or a root pouch so that in the majority of instances the type of lesion as well as the level and size may be (accurately) determined preoperatively. In rare instances the myelogram can be normal with a prolapsed disc. Disc prolapse may be divided into two types according to location: central and lateral. The central prolapses lie anterior to the theca while the lateral ones are between the theca and the intervertebral foramen. Central prolapses present a varying picture which depends on the size of the lesion and the type of cauda equina arrangement present. A constriction or hourglass appearance usually exists in the moderate prolapses when the prolapsed disc is a larger interruption of the contrast medium column results in a gap design. The contrast column with a central area of reduced radiolucency is less common. In the lateral film all of these types are seen as an invagination of the medium by the misplaced disc. In some instances the anteroposterior views may be normal and the lateral film shows the only abnormality. The defect produced by the laterally placed prolapsed disc varies with its position, as when it is medially placed it produces a greater deformity than when it is extremely lateral. In fact it may be so far lateral as to cause no abnormality in the myelogram.

The intermittent disc is best visualized by voluntary hyperextension of the spine during roentgenography and often a normally taken view fails to

7 Primary cholesteatoma of the mastoid due to the presence of embryonal cells in the temporal bone described by Amersbach as epidural cholesteatoma, or mucocele of the mastoid cells. Roentgenologically this is very much similar to the condition in the author's case, but the clinical picture is very different.

8. Benign tumor The author's case might have been a benign tumor but he was unable to explain the alteration of the mastoid as a consequence of such tumor. Surgical intervention revealed a large cavity 3 mm. from the bony cortex, filled with gray tissue and waterlike fluid. This neoplastic mass which was attached to the dura of the middle cranial fossa was removed and histological examination revealed it to be connective tissue. A tumor of this type was named "meningioma" by Cushing. Meningiomas originate from endothelial arachnoid cells enclosed in the dura mater are somewhat prevalent along the sinuses, and communicate with the dura of some of the cranial nerves. The author's case could be classified an endothelioma, as this often occurs in the petrous bone and clinically gives the symptoms and signs of an endocranial tumor.

JOSEPH M. A. PAPP, M.D.

Kubanyi A : The Treatment of Trigeminal Neuralgia by Intracranial Coagulation of the Gasserian Ganglion (Sur le traitement de la névralgie du plexus trigéminal par l'électro-coagulation intracrânienne du ganglion de Gasser) *Lyon chir* 946, 4 68

The author opens with the statement that when comparisons are made of the efficacy of various methods of treatment for any one disease, those treatments longest in use usually show up in a more favorable light than the newer treatments. He believes, however, that the relatively new operation of coagulation of the gasserian ganglion for the treatment of trigeminal neuralgia first propounded by Kirschner in 1931 merits wider consideration and use. His experience with 301 patients so treated would seem a wide enough one for the expression of an opinion.

A review of the various methods of treatment of trigeminal neuralgia shows that operative difficulties, recurrence of symptoms, and untoward side effects may occur no matter what form of treatment is used. The alcoholic injection of the terminal branches of the nerves or of the lower two divisions at their foramina of exit, the early operation of ganglion extirpation by Frazer, the common operation of neurotomy of the root proximal to the ganglion either by the subtemporal route or by the newer and more difficult suboccipital approach, and the latest method, advanced by Sjögqvist in 1938 of performing tractotomy on the descending sensory pathways of the trigeminal nerve within the lower brain stem, are all reviewed briefly by the author.

The accurate coagulation destruction of the gasserian ganglion presupposes the accurate localization of the ganglion before operation. The author has

carefully worked out the anatomical co-ordinates for the passage of the insulated trocar with its central electrode and the operation done under general intravenous anesthesia is always performed under roentgenographic control in the department of roentgenology. The instrument is passed through the foramen ovale the ganglion lying at a distance of 19 mm. from the foramen. Repeated coagulation may be necessary to obtain complete relief but while pain is completely abolished, normal sensation may begin to return as early as 3 weeks after coagulation.

Among the author's 301 patients, 317 were considered cured. Coagulation was performed twice in 75 patients, 3 times in 85 patients, and 4 times in 11 patients. Postcoagulation paresthesias occurred, apparently in much the same way as they occasionally occur after operative resection of the posterior root. An occasional hemiplegia resulted, as well as some occasional damage to the extraocular muscles, and the keratitis of anesthesia. JOHN MARTIN, M.D.

Bajer A.: Contribution to the Problem of Post-operative Anesthesia Dolorosa of the Trigeminal Nerve (Příspěvek k problému pooperační anestezie dolorosa trojklanného nervu) *Čas listy* 946 577

A middle aged woman who experienced a severe menopause and was now suffering from high blood pressure (120 mm. Hg) developed a typical neuralgia of the trigeminal nerve at 60 years of age and was operated upon by Kirschner's coagulation of the gasserian ganglion on a different occasion without permanent relief. She was then subjected to a furta porture radiotomy with interruption, through the occipital route of the lower and outer two-thirds of the sensory root of the trigeminal nerve on the left side. There was immediately a loss of sensation over the region supplied by the first and second branches of the trigeminal nerve, with lowered sensitivity to touch and lack of the sensations for heat, cold, and pain on that side. The corneal reflex was absent and the patient complained of seeing double and of spasms of the musculature of the left side of the face. The blood pressure dropped to 135/70 mm Hg.

At re-examination 2 months later there was present a mild enophthalmos and narrowing of the ocular cleft (Horner's syndrome) on the left side, a lowered corneal reflex, hypotonia of the left masticatory muscle group and mild deflection of the tongue to the left side. The left palatal arch was lowered and narrowed, there was lowered sensitivity over the left half of the mouth cavity, larynx, and anterior two-thirds of the tongue, and a lowered pharyngeal reflex on that side. Over the area supplied by the left trigeminal nerve there has persisted a lowered sensation to touch and nonsensitivity for heat, cold, and pain, however pressure over this area produced a burning pain which was most pronounced over the left zygomatic region, and pressure over the sympathetic plexus of the left carotid produced burning pains over the left half of the face which however

persisted for but a short time. At the same time there occurred a marked dilatation of the left pupil. There was also increased sweating over the left half of the face accompanied by an abnormal flushing.

The author recognized these manifestations as an irritative hyperpathia and a sympathalgia or oculo-gia, of the sympathetic nerves and ganglia of the left side of the neck and head and maintained that they correspond to the *anesthesia dolorosa* as described by Olivecrona, that they are not related to a recurrence of the trigeminal neuralgia and that they do not require further surgical interference. The irritative hyperpathy could not be influenced by medication but did not trouble the patient very much. The sympathalgia was controlled by giving extractum fungi secalis (o r) with luminal (o os).

SPINAL CORD AND ITS COVERINGS

Begg, A. C. Falconer M. A., and McGeorge M.
Myelography in Lumbar Intervertebral Disc Lesions. *Brit J Surg.*, 1946 34 141

The authors present results from 86 myelograms done for the investigation of low back pain and sciatica in an attempt to clarify the controversial issues raised in the past regarding the value of this procedure.

Four separate groups of disc lesions are described:

1. Projections
2. Intermittent prolapses: the intervertebral protrusion which occurs only when the vertebrae are subjected to certain strains (also known as the concealed disc of Dandy)

3. Extrusions: the condition present following rupture of the annulus fibrosus with escape of the nuclear material into the spinal canal

4. Scarred discs: over a period of years the opposing surfaces of vertebral bodies may become sclerotic with bony lipping; decrease in the size of the disc space, and subsequent adhesions of the theca and extrathecal nerve roots to the back of the discs without any actual soft tissue projection.

Although their method of examination is essentially the same as that used by other investigators the authors have employed certain distinct features which need enumeration: the needle is inserted while the patient is horizontal and 3 c.c. of contrast medium (lipiodol or pantopaque) are injected. The patient stands on a vertical tilt table and the table is then tilted downward slowly. Occasionally it may be necessary to turn the patient obliquely to obtain better filling of the root pouches. As the contrast medium straddles each disc space anteroposterior spot films are taken and the tilt angle noted. After the lumbar interspaces have been inspected the tilt is reversed and the medium observed as it flows backward. Prone lateral views of the two lower lumbar interspaces are taken routinely: these have proved of help in diagnosing certain disc lesions. Oblique views rarely reveal information which cannot be ascertained from the lateral and anteroposterior views.

A recent innovation is used in demonstrating the intermittent prolapse. This consists of having the patient hyperextend the spine by raising his head and shoulders. This maneuver has shown lesions which were not apparent by the usual method of examination. No harmful effects have been observed from either the injection of the contrast medium or allowing the material to remain within the thecal cavity. Although lipiodol was usually aspirated at the time of operation, pantopaque was allowed to remain *in situ*. Follow-up roentgenological examinations have shown that this substance is slowly absorbed, at a rate of approximately two-thirds of its volume in a year.

The arrangements of the individual nerve roots composing the cauda equina have been found to conform to two general pattern types. In one, the nerve roots are separated from each other so that those about to pass from the thecal cavity are lateral while the remainder lie medially. In the other variety the nerve roots lie in two large bundles: one on each side of the midline with a wide free space between. The individual members are arranged so that the cephalic roots are anterior. The anterior wall of the theca is closely applied to the posterior surfaces of the posterior longitudinal ligament except where the lumbosacral angle is more acute than usual (as at the fifth lumbar disc) and a few millimeters of fatty tissue are interposed. This explains why disc lesions at the fourth and higher lumbar spaces affect the myelograms more obviously than prolapses at the fifth lumbar interval.

Myelographic abnormalities usually affect the thecal column or a root pouch so that in the majority of instances the type of lesion as well as the level and size may be (accurately) determined preoperatively. In rare instances the myelogram can be normal with a prolapsed disc. Disc prolapse may be divided into two types according to location: central and lateral. The central prolapses lie anterior to the theca while the lateral ones are between the theca and the intervertebral foramen. Central prolapses present a varying picture which depends on the size of the lesion and the type of cauda equina arrangement present. A constriction or hourglass appearance usually exists in the moderate prolapses when the prolapsed disc is larger; interruption of the contrast medium column results in a gap design. The contrast column with a central area of reduced radiolucency is less common. In the lateral film all of these types are seen as an invagination of the medium by the misplaced disc. In some instances the anteroposterior views may be normal and the lateral film shows the only abnormality. The defect produced by the laterally placed prolapsed disc varies with its position as when it is medially placed it produces a greater deformity than when it is extremely lateral; in fact it may be so far lateral as to cause no abnormality in the myelogram.

The intermittent disc is best visualized by voluntary hyperextension of the spine during roentgenography and often a normally taken view fails to

reveal this abnormality. The authors have found that weight bearing does not accentuate this defect as much as the hyperextension.

Extrusions of the disc material may cause obliteration or displacement of the thecal column of contrast medium.

Scarred discs are diagnosed by first noting the narrowed space and bony vertebral spurs in the plain film and, later, the defect in flow of the intrathecal contrast material. Comparison of the contrast defects with plain films show the abnormalities to be at the site of the osteophytic outgrowths and not due to soft tissue projections.

Indirect effects of disc prolapse have been noted in many instances and deserve mention. Swollen letrathecal nerve roots may result from compression by the prolapsed disc and are demonstrated by absence of filling and a band of radiolucency indicating the position of the nerve roots. Leptomeningeal adhesions may occur as a result of long standing disc lesions and produce an obstruction in the thecal column. In the anteroposterior view this has a serrated edge (in contrast to the cauda equina tumor which has a smooth contour) and in the prone lateral film there is noagination of the anterior thecal wall such as with a disc prolapse. Multiple prolapses were present in 17 per cent of the cases.

Artefacts are produced by leakage of the contrast medium outside of the limits of the subarachnoid fluid canal and the following points should be executed:

1. Perform lumbar puncture with the patient in a horizontal position. This is to prevent the additional spinal fluid pressure of an upright position.
2. The injection should not be made within several days of a previous spinal puncture.
3. Injection should be done through a fine needle and the dura and subarachnoid pierced only once.
4. Examination should be made soon after injection, the patient meanwhile remaining horizontal.

The following results were obtained in this series:

1. Of the 76 cases in which the myelogram was considered abnormal, only 2 did not reveal the anticipated lesion. In nearly all these lesions there was a high correlation with regard to the site, type and size of prolapse and the operative findings.

2. In each of the 10 cases in which the myelogram was thought to be normal, a disc lesion was found at operation. In some of these cases the intermittent type of prolapse was found, but the hyperextension maneuver had not been performed during myelography.

The authors conclude that when myelography is positive it is of value in estimating the level and type of prolapse and whether or not single or multiple discs have prolapsed. The information whether or not a prolapse is central or lateral is of value preoperatively since it determines the approach for the surgeon and avoids the unnecessary trauma which exploration would necessitate.

The authors recommend routine investigation of lumbar intervertebral disc lesions by myelography.

but state that it should not displace other clinical methods of diagnosis for disc abnormalities.

C. FREDERICK KITTLE, M.D.

PERIPHERAL NERVES

Courty, A., Cabanettes, L., and Bertrand, L.: Contusions of the Peripheral Nerves Treated by Sympathetic Block (*Contusions nerveuses et infiltrations sympathiques*). *Rev. ch. Par.*, 94, 65-66, 350.

This article concerns 11 cases of so-called contusion of the nerves treated by sympathetic block, all in the upper extremity. Some were probably contusions as the term is understood; others were probably combined vascular and nerve lesions and others could probably be classified as causalgic states. The criteria for a satisfactory sympathetic block, presumably with novocain, are not established. One tellate injection was described as being very satisfactory, and in support of this the statement was made that the hand was very warm; the block was said to last three-quarters of an hour. (Under these circumstances it is difficult to translate this article into terms useful to our concepts.)

Five cases were the result of shoulder dislocation in various positions followed by involvement of the peripheral nerve and in some cases by vasomotor states. A satisfactory stellate injection immediately relieved the vasomotor complex and tended to show the pure peripheral nerve component. In some cases oscilometric readings were found to be diminished as compared with the sound side. In 2 of these cases there was no vasomotor disturbance, and infiltration of the stellate ganglion produced immediate and dramatic improvement in the range of movement of the involved muscles. This improvement was most marked immediately after the injection but tended to fade. There was however a net improvement which was maintained after each injection.

The 6 other patients were injured in various ways. 4 received injuries from missiles in or near the peripheral nerves; in 1 patient the whole arm was pinned under a vehicle and in another a fracture of the humerus injured the nerve. Some of the injuries were mixed nerve and blood vessel lesions; others could not be diagnosed with certainty.

The last case reported was that of a patient who received an injury in January 1945 and was examined the next day. The patient stated that his paralysis followed the operation at which no lesion of the nerve or blood vessel was found. Stimulation of the nerve at operation in March showed complete interruption of conduction. In August a second operation was contemplated but the patient bumped his arm near his old wound. This was immediately followed by such improvement in the movements of the hand that operation was indefinitely postponed.

The authors present tables showing the difference in response to faradic and galvanic stimulation before and after sympathetic block. These show improvement in electrical response which parallels the

SURGERY OF THE NERVOUS SYSTEM

133

clinical improvement seen in some of the cases. It is believed that the sympathetic block decompresses the nerve. Follow up studies unfortunately were not always available.

ADRIEN VAN BRUGGEN M D

Finocchiaro R.: The Morphological Considerations of Neuroglia in the Isolated Sectioned Nerve. (Sulla morfologia del cosiddetto neurogloma da sezione nei nervi isolati) *Gior ital chir.*, 1946 : 539.

If a paralysis results after section of a nerve, there is some other factor besides the nerve section which causes it. Under normal circumstances following the section of a nerve the perineural tissue reaction favors sclerosis which impairs the function of the injured nerve.

Neurogloma following amputation results in not only a regenerative proliferation of cylinders for maturation but also a proliferation of the cells of Schwann and the fibrous cells of the endoneurium and perineurium. It has been shown that neuro-

fibrils regenerate even after cauterization of the stump or the treatment of the nerve with alcohol.

Two series of experiments were carried out on 8 rabbits in which the sciatic nerve was sectioned. In the first series the sectioned nerve was surrounded by cellophane which isolated the nerve from its blood supply with simple section as a control. The nerves were injected with alcohol in the second series, and the rabbits were killed after 60 days. It was shown that the nerves surrounded with cellophane presented the formation of a fibrous capsule although the ends were free and smooth. In the control animals a sort of detritus formed around the cut ends of the nerve. Alcohol was found to diminish the regenerative action.

The author concludes that isolation of the sectioned nerves from their blood supply does not impair the vitality of the nerve or the normal progress of the process of regeneration and cicatrization but it eliminates the participation of the perineural connective tissue in the reaction following

ARTHUR F. CIPOLLA M D

SURGERY OF THE THORAX

TRACHEA, LUNGS, AND PLEURA

Binet L., and Burstein M.: New Experiments Pertaining to Pulmonary Embolism (Nouvelles recherches sur l'embolie pulmonaire expérimentale). *Press. méd.* 946 54 633

Experiments were carried out on dogs by injecting into the external jugular vein a lycopodium powder suspended in vasoline in oil or a watery suspension of barium sulfate for the purpose of (1) studying the pulmonary circulation during the course of a pulmonary embolism (2) elaborating upon certain neurovegetative reflexes induced by the embolism and finally, (3) studying how the greater circulation adjusts itself under these conditions.

EXPERIMENTS PERTAINING TO THE LESSER CIRCULATION DURING THE COURSE OF AN EMBOLISM

The normal pressure in the pulmonary artery is 2 cm. of Hg or approximately one sixth that of the pressure in the systemic circulation. This pressure is derived from the output of the right ventricle of the heart and from the opposing resistance of the pulmonary vessels to the circulation of the blood.

If small amounts of lycopodium powder or barium sulfate are injected into the external jugular vein with 2 or 3 minute intervals between the injections a progressive rise in the pressure in the pulmonary vessels is immediately noted following the first injection. Various figures are obtained according to the dog. In some animals the pressure may reach 7 cm. of Hg before the right heart collapses, and then the pressure falls to zero. On the other hand a cardiac syncope may occur in the weaker animals when the pressure in the pulmonary artery reaches 5 cm. of Hg. Such a difference is due to the varying effective power of the right ventricle to overcome the peripheral resistance and also to the degree of adjusting reaction which is found to take place in the greater circulation.

What is the cause of such hypertension? Is it the consequence of the mechanical obliteration of the pulmonary vessels alone or of such obliteration combined with spasm?

It is hard to believe that vascular mechanical obstruction alone can produce hypertension.

The circulatory area of the lungs is very extensive and it produces mechanical obstruction in the pulmonary vessels a very large number of emboli particles seem necessary. The hypertension existing in the pulmonary artery occurs early and is very marked, revealing the existence of a very important barrier to the blood flow in the pulmonary vessels. In fact, after ligation of one of the main branches of the pulmonary artery cutting 50 per cent of the blood supply to the lungs, the pressure in the pulmonary artery reaches 3 cm. of Hg at the most. There is a hypertension of from 5 to 7 cm. could then be ex-

plained on the basis of an important vascular spasm brought on by the emboli particles.

The existence of spasm in the vessels of the extremities secondary to an embolus has been ascertained by Leriche's experiments. However the spasm of the pulmonary vessels does not seem to be of a similar nature. This spasm indeed is the direct consequence of a mechanical irritation of the arterioles. However the pulmonary artery itself does not constitute a reflexogenic zone as is the case for the arteries of the extremities. In the former case the reflex originates in the arterioles, while in the latter it originates in the arteries. Furthermore, the peripheral vasoconstriction is secondary to a stimulus of the sympathetic but this is not the case in the lungs. The hypertension in the lesser circulation is independent of the sympathetic, since hypertension in the lesser circulation still exists after bilateral thoracic sympathectomy. Furthermore the authors have shown in a lobe isolated as far as its blood supply is concerned but with an intact nerve supply that novocain infiltration of the stellate ganglion does not produce any vasodilatation of the vessels of the lesser circulation, and the faradization of the same ganglion produces a vasoconstriction not at all similar to the increase in pressure registered during the course of an embolism. Therefore the mechanism of the hypertension seems to be operating through an autonomic reflex independent of the central nervous system.

To summarize, a small embolus in the lungs produces the same circulatory changes and the same obstruction as a large embolus which constitutes a mechanical barrier to the blood flow. If the concept of vascular spasm is accepted. The important factor is not the size of the embolus but the vasoconstriction produced.

Because of the intravascular irritation the functional consequences of a small embolus, by far exceed the mechanical consequences. Large and small emboli can be considered as similar in view of the concept of a spasm.

THE REFLEXES ORIGINATING IN THE LUNGS DURING THE EMBOLISM

A local vasoconstriction is determined by the pulmonary embolus. Can the existence of remote reflexes be proved?

The existence of a reflex bronchospasm through the vagus nerve was already demonstrated in previous experiments. The experiment on the vagal reflexes by producing a small nonfatal embolism following the injection into the external jugular vein of a c.c. of lycopodium powder suspended in vasoline in oil in a 10 to 20 kgm. dog was repeated. Kymographic tracings of the pressure in the carotid as well as if the branch were registered on the vagotomized or atropinized dog the embolism in

jection did not produce any change in the pressure curve nor in the bronchogram. In the animals with an intact vagal innervation and especially in animals which received but only weak doses of eserine (eserine increases the effects of vagal stimulation) the embolizing injection determined a bradycardia and a bronchospasm of varying intensity which disappeared immediately after section of the vagi. Therefore, it seems to be a reflex vagal stimulation due to an innervation of the endovascular nerve endings by the embolizing particles.

The vagal centers during the embolism are stimulated by opposing stimuli there is a marked and precocious venous bradycardia during the embolism and it is known that a tachycardia (Bainbridge reflex) is produced by hypertension in the right auricle because of diminution of the vagal tone. Thus, there are two coexisting vegetative reflexes during the embolism—one originating from the lung and the other originating in the right auricle. This explains why the bradycardia may be absent during the embolism especially if the venous hypertension is found to be marked.

The hypotension in the greater circulation is of cardiac origin and is the immediate result of a diminished cardiac output secondary to venous stasis and insufficient flow of blood into the left auricle. In other words the hypotension is caused by a disturbance in the returning circulation and is absolutely independent of any reflex of pulmonary origin.

STUDY OF THE REACTIONS OF ADAPTATION IN THE GREATER CIRCULATION DURING THE PULMONARY EMBOLISM

It is known during the embolism that the rise in venous pressure is rapid and precocious, which indicates the insufficiency of the right ventricle, which cannot completely empty itself with venous stasis as a direct result. On the other hand the rise in pressure occurs very early in the pulmonary artery and finally the pressure falls in the left auricle secondary to a diminished output of the right ventricle.

The precocious hypertension and the hypotension in the left auricle indicate that in spite of its efforts, the right ventricle is unable to push into the lungs all the blood that it receives hence, venous stasis progressive divergence of the blood from the active circulation, disturbance in the distribution of the blood between the arterial and venous systems decreased output of the left ventricle and finally decreased volume of the circulating blood occur.

A peripheral vasoconstriction is the adaptive reaction of the organism to such a decreased cardiac output.

There exists then during the embolism hypertension in the lesser circulation and hypotension in the greater circulation and a vasoconstriction in both. This vasoconstriction is the cause of the hypertension in the lesser circulation and the consequence of the reduced circulating blood in the greater circulation.

The decrease in the output of the left auricle is related to the inability of the right ventricle to adapt itself to the pulmonary obstacle.

The postembolic circulatory collapse produces a peculiar state of shock, characterized by hypertension in the pulmonary artery venous hypertension and peripheral vasoconstriction which maintains the pressure in spite of a diminished cardiac output.

There are two types of circulatory collapse—one with vasodilatation and one with vasoconstriction. The former occurs during histaminelike shock or follows inhibition of the vasoconstrictor centers or paralysis of the sympathetics. The latter is always secondary to a diminished cardiac output. It may be due to acute cardiac insufficiency or to diminished blood volume secondary to hemorrhage plasma loss (as in traumatic shock, burns) or water loss (as in profuse diarrhea). Pulmonary embolism represents a new example of circulatory collapse with vasoconstriction secondary to a disturbance in the distribution of the blood between the arterial and venous systems.

To summarize experimental pulmonary embolism produces a particular state of shock with hypertension in the lesser circulation hypotension in the greater circulation and vasoconstriction in both. It is related to a disturbance in the distribution of the blood between the arterial and venous systems, secondary to a spasm in the pulmonary vessels.

The embolism produces, besides a bronchospasm a reflex vasoconstriction in the pulmonary vessels independent of the sympathetic innervation and also certain remote reflexes by stimulation of the vagus. There is a peripheral vasoconstriction during the embolism secondary to a diminished cardiac output.

GERARD GAGNON, M.D.

Findlay, C. W. Jr. and Sweet, R. H.: Aerosol Penicillin as a Therapeutic Adjunct in the Preparation of Patients with Suppuration of the Lung for Pulmonary Resection. *J. Thorac. Surg.* 1947 16: 81.

Bronchial secretions in patients with pulmonary suppuration have often been a source of trouble at operation to both the surgeon and the anesthetist. The induction of anesthesia has frequently been difficult. Numerous aspirations of the trachea and bronchi during operation have delayed the surgical procedure, and in some instances death has occurred on the operating table because of the drowning of the patient in his own secretions.

Parenteral and oral chemotherapy have been of considerable value in preparing patients with bronchiectasis or lung abscess for surgery. In spite of this treatment complications during operation due to bronchial secretions have continued. In an attempt to decrease further these bronchopulmonary exudative processes, aerosol penicillin inhalations have been used preoperatively at the Massachusetts General Hospital. The present report was based upon careful studies of the first 20 patients subjected to the treatment.

The authors first describe the technique. They used oxygen to nebulize the drug. In most instances 50,000 units of sodium penicillin dissolved in the nebulizer. Each 8 c.c. of penicillin solution contains 0.25 c.c. of a 50 per cent oil of peppermint solution in isopropyl alcohol. The patient occluded the open side arm of the Y tube only during inspiration. At all other times the oxygen was diverted from the nebulizer via the open arm Y tube. The breath was held for 5 seconds after each inspiration. It usually took 30 minutes for the administration of 1 dose of penicillin. Usually 8 treatments were given each day.

In the series of 20 cases, 14 patients had bronchiectasis. Three patients had lung abscess and there were 3 patients with bronchogenic carcinoma with associated bronchitis, bronchiectasis, or cavitation.

The authors present case studies of all 20 patients and the results. It was found that the odor of bronchial secretions which were foul at the onset was practically eliminated in every instance. There was thinning of the sputum. The sputum production was reduced. The anesthetic course was uncomplicated in 15 of the 20 patients. The postoperative course was much easier.

The authors point out the importance of concomitant therapeutic measures in the preoperative preparation. Postural drainage, bedrest and elevation of the blood proteins and also the intramuscular use of penicillin is important. Sulfadiazine should be used to control the obvious penicillin-resistant organisms in the sputum. The authors stress the individualization of patients for therapy.

PAUL MARSHALL, M.D.

Santy, P., and Bérand, M.: Dangers of Routine Pneumotomy in One Stage for Surgical Treatment of Pulmonary Abscess (Les dangers de la pneumotomie systématique en un temps dans le traitement chirurgical de l'abcès du psoeumon). *Presse med.* 940, 54, 525.

Experience gained from the treatment of 200 patients with pulmonary abscess brings the authors to the following conclusions:

Employment of one operative pneumothorax in the treatment of lung abscess in the absence of sufficient firm and extensive pleural adhesions is fraught with great danger. The authors are vigorously opposed to one stage pneumotomy in the treatment of pulmonary abscesses of recent origin because of the danger of operative pneumothorax and septic inoculation of the pleura. In spite of the immediate application of penicillin and sulfonamides, the prognosis of septic pleurisy is very grave. Two entirely different conditions should be distinguished when one speaks of pulmonary abscess: accidental tear of the pleura in the course of rib resection and incision of the pleura during the course of pneumotomy

after the abscess had been exposed. In the first case the accident is of no great importance because rupture of the pleura and aspiration of the air from the pneumothorax usually prevent complications. In the second instance the adhesions may give way on physical exertion or following a violent attack of cough. In such a case a retraction of the lung toward the mediastinum may follow separation of the adhesions or an exceedingly septic pyopneumothorax may develop in spite of drainage of the pleural cavity and the administration of sulfonamides and gangrene serum.

Two objections to a two stage operation for pulmonary abscess have been advanced: danger of pneumonia and the difficulty encountered in locating the pulmonary cavity deformed by compression. Bronchovascular dissemination may be avoided by limiting the resection to one or two ribs. Of 80 patients who underwent pneumotomies in 1 stage, only 1 patient died after the first stage. He was of advanced age and had abstained from the use of alcohol.

As a rule, pleural symphysis provoked by the incision of locoforn gauze prevents pneumothorax. The danger of such a complication exists only in a patient with an abscess of the middle lobe. In such a case not the parietal but the interlobar pleura may be torn, but such a complication cannot be ascribed to the first stage of the operation. In certain cases evacuation of a lung abscess through the bronchi may take place under the influence of a compression created by the first stage of the operation. A spontaneous cure may thus result. A careful roentgenologic examination never fails to reveal the location of the abscess after the first stage. As to multiple abscesses, a one stage procedure does not facilitate the attempts to localize them.

Only in extremely septic conditions in which delay may be dangerous do the authors advocate one stage procedure.

Their attitude toward chronic abscesses of more than 3 months' duration is less severe because immediate pneumotomy is not fraught with danger.

JOSEPH K. NASSAR, M.D.

Coorsand, A., Himmelsstein, A., Riley, R. L., and Lester, C. W.: A Follow Up Study of the Car diopneumotomy Function in 4 Young Individuals after Pneumectomy. *J. Thorac. Surg.* 1947, 6, 30.

This article reports a basic physiologic study of what has happened to 4 patients who underwent left pneumectomy in childhood or early adolescence now that they have passed their period of active growth.

Three of these cases have been previously reported at an earlier age of the patients, as they were studied at regular intervals since operation. The studies concerned the determination of lung volume, ventilating efficiency of the chest bellows, efficiency of alveolar ventilation and the state of respiratory gas exchanges in the lung and arterial blood at rest and during moderate and exhausting exercise.

One of these patients, who showed no evidence of pulmonary overdistention performed under the tests, in a way quite comparable to normal controls.

Two of the patients, however, who had evidence of pulmonary overdistention under conditions of exhausting exercise showed a reduction in oxygen reserve and a rather marked degree of oxygen unsaturation in the arterial blood.

In 3 of the subjects the blood pressure in the right ventricle was determined by catheterization technique and revealed no hypertension. In 1 instance the pressure within the pulmonary artery was recorded and found to be normal.

The techniques by which the various data were obtained are outlined, and graphic representation of them is frequent.

HIRAM T. LANGSTON, M.D.

Meade, R. H. Jr., Kay, E. B. and Hughes, P. A.: A Report of 196 Lobectomies Performed at Kennedy General Hospital Chest Surgical Center from 1943 to 1946 with 1 Death. *J. Thorac. Surg.*, 1947, 16, 16.

This truly amazing report comprises the lobectomies done between November, 1943 and April, 1946 at one of the Army Chest Surgical Centers, on 190 patients. By the time this paper was read in May, 1946 the series had actually grown to 236 lobectomies with only 1 fatality (approximately 0.5 per cent).

The patients were in a young age group, the largest number being between 20 and 30 years old. Bronchiectasis was the most common disease requiring lobectomy followed in decreasing order by cyst (8 cases). There were 4 bilateral lobectomies. Complications occurred in 27 cases, 15 of them being empyemas (7.5%). Transient jaundice occurred in 7 cases, hemothorax requiring drainage in 1 case and pneumothorax in 2 cases. A focal cerebral lesion was encountered once; it was presumed to be due to an embolus but recovery took place. Atelectasis of a stubborn character occurred once. Four of the empyemas occurred without evidence of bronchial stula.

The preoperative, operative, and postoperative management of these patients is given in some detail, but particular reference being made to the cases of bronchiectasis. Here the preoperative efforts, directed to reducing the quantity of retained sputum as well as the severity of the associated infection, included drainage by posture and intensive infection therapy by intratracheal administration of penicillin. The operations were carried out under the protection of a with controlled respirations was the technique frequently employed. Individual ligation of the drainage of the pleural cavity was routine practice. Water was bronchoscopy at the close of the operation. Interruption of the phrenic nerve was frequently practiced to prevent overdistention of small

amounts of remaining lung tissue for deep seated pain or discomfort and to diminish the pull on incompletely covered bronchial stumps.

HIRAM T. LANGSTON, M.D.

Stephens, H. B., Harroun, P. and Bockert, F. E.: The Use of Curare in Anesthesia for Thoracic Surgery. *J. Thorac. Surg.*, 1947, 16, 50.

This article relates the experience of the authors with 75 patients undergoing major types of thoracic surgical procedures for which curare anesthesia was used. The present purified product of dependable action is marketed under the name of Intocostin.

The use of the cautery in intrathoracic operations can be allowed when a nonexplosive anesthetic agent such as nitrous oxide is used and controlled respiration technique is possible if apnea is produced by the intravenous administration of curare.

The technique evolved is as follows:

The patient is heavily medicated with a short acting barbiturate, morphine and scopolamine. Nitrous oxide and oxygen are given by means of the face mask, pentothal sodium being used if necessary to achieve satisfactory anesthesia. The patient's requirements of nitrous oxide and oxygen are noted as a basis for later maintenance at this time. When a pharyngeal airway has been placed and it is determined that artificial respiration can be maintained by pressure on the breathing bag, a dose of curare (100 mgm. for adults) is given intravenously (30 seconds). When apnea occurs (30 to 60 seconds) manual inflation is started. When maximum relaxation is achieved an orotracheal tube is passed (An additional 100 mgm. of curare are given if necessary). The tracheal tube is connected to the gas machine, a breathing bag and soda lime canister are used and the patient is maintained by the requirements determined during the period of induction. The patient is then properly positioned. A continuous drip of 5 per cent glucose is started so that additional curare can be given with this if necessary.

In children the barbiturate is omitted, but avertin (from 100 to 150 mgm. per kilogram body weight) is given and cyclopropane is used to facilitate the introduction of the tracheal tube. Anesthesia is continued with nitrous oxide and oxygen. Just before the pleura is opened enough curare is given through the intravenous drip of 5 per cent glucose to stop respirations (from 40 to 60 mgm. for a 2 to 4 year old child). Rhythmic inflation is achieved by a T tube in the circuit which can be occluded by the anesthetist's thumb.

Various other details in the management of this technique are clearly pointed out.

There were 8 hospital deaths in this group of 75 patients and the anesthetic may have been partially responsible for 3 of them. The types of surgery for which this technique was used however included numerous very extensive procedures. The maximum length of operation was 10 hours and 40 minutes and 790 mgm. of curare were used.

It is believed that curare has no cumulative effect and possesses no anesthetic properties per se. Prostigmine has not effectively promoted the return of intercostal activity but this activity should be well established before complete control of the patient is relinquished by the anesthetist.

No significant changes in kidney and liver function tests or electrocardiogram tracings have been found in 44, 50 and 35 cases respectively.

HEART AND PERICARDIUM

Bing, R. J. Vandam, L. D., and Gray, F. D., Jr.: Physiological Studies in Congenital Heart Disease. Procedures. *Bull. Johns H. Univ. Hosp.* 947:80, 7.

Recent studies which led to the surgical treatment of congenital heart disease with cyanosis have stressed the physiological importance of the diminished rate of pulmonary blood flow in the production of anoxemia. Varying types of congenital malformations of the heart with reduced volume of circulation through the lungs have been described. These include cases with pulmonary atresia or stenosis alone or in combination with other malformations to form the tetralogy of Fallot cases with a single ventricle in which the pulmonary artery arises from the rudimentary outlet chamber and cases with truncus arteriosus, in which the circulation of the lungs courses through the bronchial arteries.

The theoretical bases of the calculations made in the course of the physiological studies undertaken are the following:

1. Measurement of the circulation through the pulmonary artery and the systemic circulation. The output of the heart may be calculated with the following:

Cardiac output (ml. per min.) equals

$$\frac{\text{O}_2 \text{ intake (ml. per min.)}}{\text{O}_2 \text{ content of arterial blood (vol. per cent) minus O}_2 \text{ content of mixed venous blood (vol. per cent)}}$$

or

Cardiac output (ml. per min.) equals

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of mixed venous blood (vol. per cent) minus CO}_2 \text{ content of arterial blood (vol. per cent)}}$$

The oxygen content of the pulmonary vein (vol. per cent) equals the percentage O₂ saturation of the pulmonary vein times the O₂ capacity (vol. per cent).

The blood flow through the pulmonary artery was subsequently calculated with the equations

Pulmonary artery flow (ml. per min.) equals

$$\frac{\text{O}_2 \text{ intake (ml. per min.)}}{\text{O}_2 \text{ content of pulmonary vein (vol. per cent) minus O}_2 \text{ content of pulmonary artery (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of pulmonary artery (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

2. Measurement of systemic blood flow is obtained with the following formula

Systemic flow equals

$$\frac{\text{O}_2 \text{ consumption (ml. per min.)}}{\text{O}_2 \text{ content of arterial blood (vol. per cent) minus O}_2 \text{ content of right auricular blood (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ production (ml. per min.)}}{\text{CO}_2 \text{ content of right auricular blood (vol. per cent) minus CO}_2 \text{ content of arterial blood (vol. per cent)}}$$

3. The total volume of blood perfusing the lung (pulmonary capillary flow) is determined with the use of the following formula

Pulmonary capillary flow (total pulmonary blood flow) ml. per min. equals

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of blood reaching alveoli (vol. per cent) minus CO}_2 \text{ content of pulmonary vein blood (vol. per cent)}}$$

4. In determining the shunts the pulmonary capillary flow is taken to represent the amount of blood reaching the lung through the pulmonary artery and through the collateral vessels. Consequently the measurement of the total pulmonary artery and capillary flows permits the determination of the volume flow through the collateral circulation to the lung by the following formula

Collateral circulation to the lungs (ml. per min.) equals pulmonary capillary flow (ml. per min.) minus pulmonary artery flow (ml. per min.)

In cases of the tetralogy of Fallot the systemic flow exceeded that through the pulmonary artery the difference between the two volume flows representing the shunt from the right ventricle through the interventricular septal defect or the overriding aorta. Therefore it was possible to calculate the intracardiac shunt from right to left by the following formula

Intracardiac shunt right to left (ml. per min.) equals volume of blood flow through the systemic circulation (ml. per min.) minus volume of blood flow through pulmonary artery (ml. per min.)

5. Calculation of the mixed venous pulmonary flow. The mixed venous pulmonary flow may be defined as the volume of blood which, after its return to the right auricle, ultimately reaches the pulmonary alveoli. Since it is the only component of the circulating blood which becomes effectively oxygenated in the alveolar space, it is referred to as the effective pulmonary blood flow

Effective pulmonary blood flow (ml. per min.) equals

$$\frac{\text{O}_2 \text{ consumption (ml. per min.)}}{\text{O}_2 \text{ content of pulmonary vein blood (vol. per cent) minus O}_2 \text{ content of right auricle blood (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

or

$$\frac{\text{CO}_2 \text{ output (ml. per min.)}}{\text{CO}_2 \text{ content of right auricle (vol. per cent) minus CO}_2 \text{ content of pulmonary vein (vol. per cent)}}$$

Percentage of total mixed blood reaching lung equals

$$\frac{\text{Effective pulmonary blood flow}}{\text{systemic blood flow}} \times 100$$

The resistance in the systemic circulation was calculated by the formula of Aperia
Peripheral resistance equals

$$\frac{\text{Mean systemic blood pressure}}{\text{flow in systemic circulation per second}} \times 1332$$

On the basis of these formulas and the technical procedures described reports will be published dealing with the preoperative and postoperative findings in patients with a reduced pulmonary blood flow, and with investigations in individuals with increased circulation through the lungs. SAMUEL KARLO MD

Decker P : Avenues of Approach in Pericardectomy (Les voies d'accès à la péricardectomie) *Press méd* 1947 55 59.

At the present time there are two means of access to the pericardium in general use for the treatment of adhesive fibrous pericarditis. These are the extra pleural, or interpleural, anterior approach with resection of the ribs and costal cartilages 3 through 6 and the left transpleural approach through the sixth intercostal space without the resection of any ribs.

Up to the present time most pericardial operations have been carried out through the anterior opening, but the author is of the opinion that the lateral, transpleural approach offers many advantages and more actual safety than the more common type of operation. He points out that the purpose of pericardectomy is not to uncover all of the heart, but rather to uncap it, as one would uncap any rigid box. The safest and most effective place for such an uncapping process is generally accepted to be the left ventricle. Uncapping the right ventricle might result in sudden and fatal dilatation of that chamber of the heart. The fragile auricles must be avoided because they are so easily damaged. Even the inter-ventricular septum must not be molested so as not to interfere with the support of the tricuspid valve.

The author recognizes that the anterior approach through the mediastinum allows the use of local anesthesia, and that, also, such an approach may be necessary when the pleural space is frozen and obliterated. However he prefers to do a pericardectomy under general anesthesia in any type of operation. The anterior approach leads to the right, not the left ventricle and therefore it may actually be inconvenient. Furthermore the patient is left with a permanent skeletal defect, and the bounding heart easily seen under the soft chest wall, may be a source of concern to the patient. By means of the transpleural lateral approach, pleural lysis can be accomplished if that is necessary, the left ventricle is easily accessible, the phrenic nerve can be easily visualized and protected, and by such an approach a greater total number of various lesions are more easily managed than when they are attacked through the mediastinum.

ESOPHAGUS AND MEDIASTINUM

De Vernejoul and Metras II : Esophagectomy for Cancer of the Thoracic Esophagus. Intra-thoracic Gastroesophageal Anastomosis. Three Observations. (Esophagectomie pour cancer de l'oesophage thoracique. Anastomose gastro-oesophagienne intrathoracique. Trois observations)

De Vernejoul and Metras II : Juxta-cardial Ulcer Gastrectomy by the Left Transthoracic Route. Two Observations (Ulceres juxta-cardiales. Gastrectomie par voie thoracique gauche. Deux observations)

Ballivet : Left Transthoracic Esophagogastricectomy for Cancer Placed High on the Lesser Curvature. Extending to the Cardia (Esophagogastricomie par voie thoracique gauche pour cancer haut situé de la petite courbure propagée au cardia) *Mém Acad chir. Par.*, 1946 72 513

All of the 6 operations reported consisted in extensive resection of the esophagus and stomach by the left transthoracic route with immediate esophagogastric suture done by the technique common in America and Scandinavia. There was only 1 death, which was sudden without pain and characterized by dyspnea and collapse. A partial autopsy which did not include the heart and blood vessels, did not reveal the cause.

d Allaines added 2 cases with sudden death following this operation, from his own personal experience. No autopsy report of either was given. One patient died immediately after the operation (he sat up suddenly while being transported from the operating table to bed and died in syncope) and the other died the next morning with sudden pain in right chest and collapse resembling that of a massive pulmonary embolism.

Five of the 6 patients recovered from the operation and today have put on weight and are without evidence of recurrence. One of these patients drank some milk against instructions and developed a fistula which necessitated a jejunostomy. This case demonstrated the occasional value of jejunostomy or gastrostomy in these patients. However these procedures are not approved of generally especially when they are done preoperatively as the distortion and fixation of parts with the subsequent adhesions make the subsequent transthoracic stage of the operation more difficult. This objection applies also to the combined operation with preliminary laparotomy for mobilizing the stomach and to the transthoracic approach on the right side where of course a preliminary laparotomy with mobilization of the stomach is necessary. The transferring of the esophageal stump across the aorta to the left side in high resections of this organ is also condemned as well as the argument that the right transthoracic resection is of advantage because injury to the left pleura is less frequent than injury to the right pleura when the approach is made from the left side. It is pointed out in this connection that pleural injury in this operation is of no consequence.

On the whole d Allaines thinks that this series of 6 cases of left sided transthoracic resection with 5

SURGERY OF THE ABDOMEN

GASTROINTESTINAL TRACT

Lanzetta, A.: Peroral Division and Extramucosal Cardiomycotomy in the Cure of So-Called Cardiospasm. (La divisione perorale la cardiomiotomia extramucosa nella cura del così detto cardiospasma) *Palchikoe sez. hlr* 946 53 235

In the period from 1931 to 1942 11 cases of cardiospasm were treated by conservative means with the Plummer sound, and favorable results were obtained in all. Following an aerial bombardment the sound was destroyed and then Voldroni resorted to extra mucosal cardiomycotomy or Heller's operation for the treatment of 11 cases, 1 being a recurrence of 1 of the cases treated conservatively.

The operation was performed through a median supraumbilical incision. The anterior wall of the cardia was incised down to the mucosa, the incision extending from the dilated esophagus to the anterior wall of the stomach for a distance of 1 or 2 cm. The length of the incision varied from 6 to 12 cm. The incision was then closed transversely in layers. In 4 cases the left vagus was also sectioned. The results obtained were very good in all of the cases, even in those in which the patients were not able to swallow liquids or solids.

In comparing the 2 methods, the author recommends that because of its simplicity the conservative method of using Plummer's sound should first be tried. Heller's operation should be reserved for cases not responding to conservative measures. Should this operation also prove unsuccessful, an esophagogastrostomy could be done. However the author believes that this would rarely have to be resorted to, if the previous procedures were carried out properly.

LEONARD J. PROCTOR, M.D.

Bergeret and Ollivier: Inflammatory Tumors of the Stomach (Les tumeurs inflammatoires de l'estomac) *Rev. ch. Par* 1946, 65 297

The authors prefer the term "granuloma" or "chronic phlegmon of the stomach" to "inflammatory tumors" which is the popular designation for these lesions in France. The discussion is limited to primary inflammatory tumors and to those following ulcer. The authors collected 48 cases, 1 the former type and a few cases of the latter type. In many cases inflammatory tumors have been taken for carcinomas and the patients have been subjected to extensive operations whereas these tumors have a tendency toward spontaneous regression. Also tumors developing after ulcer will frequently respond to prolonged medical treatment. Furthermore once the surgeon is aware of the benign nature of the lesion, gastrectomy can be less radical.

A brief review of cases of inflammatory tumor simulating cancer reported in the literature is presented, beginning with Terrier's case in 1904.

Inflammatory tumors of the stomach occur twice as frequently in males as in females and 5 percent occur in patients between the ages of 30 and 60 years. In more than one-third of the cases there is a history of gastric disturbances in the form of postprandial pain for a period of years. These symptoms are not much more severe in the cases of tumor following ulcer. In 2 cases the first disturbances appeared shortly after epigastric injury and after a fall causing a bruised back respectively.

In its primary form, inflammatory tumor is nearly always a complication of chronic gastritis with characteristic interstitial, atrophic, or hypertrophic lesions. Frequently there is no roentgenologic evidence of ulcer in such cases. Lesions may vary from a simple reddening of the mucosa in atrophic gastritis with or without posterior perigastritis to induration or the formation of an antral mass adherent to the liver and pancreas resembling a neoplasm even at operation. It is possible that microbic invasion is favored by these tiny superficial erosions. The origin of the gastritis is obscure, and the authors can throw little light on this aspect except to emphasize the infrequency with which alcoholism seems to play a part as contrasted with the apparently important significance of this factor in phlegmon of the stomach. The possible significance of an acute intermediary phase between these chronic affections and the development of the inflammatory tumor has been suggested. However the authors believe that such a development is likely only in a small number of cases, since initial febrile interludes have been reported in less than one-fifth of the patients. In some instances a hematogenous or lymphatic route of infection has seemed probable. The gastric wall has no special immunity to pathogenic organisms. One rarely have foreign bodies or food particles been regarded as related to the inflammatory process. Bacteriologic studies were made in only 4 cases, revealing hemolytic streptococci in 2 cases and hemolytic staphylococci and gram positive cocci in 2 other cases respectively.

The primary tumors may appear subacute, chronic, stenosing and extraorbital. In the subacute forms attention to the patient's history and the symptoms and course of the affection, rather than the laparotomy findings, should help to avoid dangerous and futile extirpations. Diagnostic features of the chronic stenosing and chronic non stenosing forms are described as well as types developing from ulcer. Localized hypertrophy of the gastric mucosa simulating neoplasm is not included in this study, only diffuse infiltrations of the other layers of the gastric wall, with or without ulcer. It is better to base the diagnosis on clinical and roentgenologic findings than on laparotomy findings. There is a history of pain and vomiting as described, and emaciation in one half of the cases. Fever is rarely

encountered but hemorrhage from the mouth or anus occurs in about 1 of every 5 cases. There may be slight jaundice. In less than one-half of the cases, abdominal palpation will reveal abnormal resistance or tumor especially in the epigastric region and much less frequently in the right or left periumbilical region. The size of the tumor may vary from that of an egg to that of an adult head. Fixation depends upon the dimensions of the tumor. The course is fairly rapid, and more than two-thirds of the patients come to operation within 6 months or less after onset. Acute exacerbations are rare. None of the characteristic roentgenologic features such as diverticula, absence of global retraction of the stomach, or mucosal integrity would suffice per se to exclude cancer but the presence of several signs together with some others not seen in cancer may serve to identify the lesion. Gastroscopy is a valuable aid especially in the differentiation of cancer from neoplasm. Cutler recommended preoperative biopsy but this is not a reliable aid. Nor can glandular biopsy be said to be decisive. Perhaps a gastrotomy made at the point where one would expect to perform gastroenterostomy in the event of positive findings would prove the best method for establishing the integrity of the mucosa. However exploratory laparotomy has not proved of value to date.

In the differential diagnosis one has to consider cancer syphilis and tuberculosis. For inflammatory tumors about an ulcer treatment resolves itself into ulcer therapy. Medical treatment has yielded good results in some cases. It should at least diminish periculous inflammation, thus rendering surgery less difficult and dangerous. Once the benign nature of the lesion is ascertained as little tissue as possible should be removed. In primary tumors of inflammatory nature a few months of medical treatment will result in cure. Because of confusion with cancer nearly all of the afflicted patients are subjected to gastrectomy. The mortality rate is 50 per cent, whereas in gastroenterostomy the mortality rate was 0. Gastroenterostomy is however indicated only in the presence of a mass causing serious obstruction and which cannot be extirpated.

EDITH SCHIARCHÉ MOORE, M.D.

Bradley W F Small, J T., Wilson J W and Walters, W: Gastric Neurectomy. *J Am Med Ass* 1947 133 459.

Anatomic consideration of the nervous structures from the cardiopulmonary plexus to the stomach has revealed great variation in pattern whereas the nerves are remarkably constant in course and distribution after reaching the stomach. In dissection in more than 100 cases at autopsy the authors concentrated, therefore, on the region above the stomach in order to evaluate the thoracic and abdominal approaches to the lower part of the esophagus for vagotomy.

In 92 of the authors' cases the gastric nerves took origin from the esophageal plexus. As the gastric nerves coursed caudad many intercommunicating

branches were observed between the right and left trunks. Small fibers, which coursed anteriorly and inferiorly over the vertebral column and the aorta were added to the gastric nerves. Communicating branches were sometimes seen to enter the musculature of the esophagus and either lose their identity or re-emerge onto the surface of the esophagus at some more caudad position. By the time the nerve trunks and branches had reached the esophageal hiatus two relatively large trunks were formed. These trunks passed through the esophageal hiatus below which their course was remarkably constant.

The 92 cases constitute 3 of the authors' groups. In the first group all of the branches between the gastric nerves and from more remote regions joined in common trunks, one on the right and one on the left side of the esophagus somewhere between the esophageal hiatus and 6 cm above the diaphragm. There were 64 such cases.

In the second group there were so many intercommunicating branches between the main trunks of the gastric nerves that a plexus was formed over a major portion of the surface of the esophagus. The branches ultimately united and formed two main trunks at the esophageal hiatus. There were 7 such cases.

The third group was characterized by the long discrete trunks without any additions to their fibers or communicating branches for a distance of 6 cm above the diaphragm. There were 21 such cases.

The fourth group was made up of the remaining 8 cases. The nerves did not have a consistent or uniform course or pattern. In cases of this type it might become difficult for the surgeon to section all the gastric nerves.

As the trunks passed through the esophageal hiatus the relative position of the right and left trunks about the esophagus was noted.

Below the esophageal hiatus the course was remarkably constant. The right gastric nerve the larger in 54 cases coursed posteriorly and to the left. After about 3 to 5 cm, this right gastric nerve divided into numerous branches. One of these branches followed the lesser curvature of the stomach as far as the incisura and another large branch followed the left gastric artery. The routine dissections did not carry beyond the division of the right gastric nerve into these branches.

The left nerve, on the other hand had a short course in the abdomen. As the left gastric nerve came to lie on the anterior surface of the stomach it almost immediately divided into numerous small branches which lost their identity in the serosa and musculature of the stomach. A branch known as the anterior nerve of the lesser curvature was consistently present behind the anterior leaf of the gastrophrenic omentum. Occasionally a small communicating branch between the right and left gastric nerves could be identified at the esophageal hiatus.

This work suggests that in slightly more than 90 per cent of cases a transabdominal subdiaphragmatic surgical approach will allow as nearly complete a division of all of the gastric nerves as a transthoracic

which had been present for years previously. In some cases in which the patient died later from other causes the autopsy examination revealed fibrous cicatrization of the giant ulcers.

The author believes that the treatment is also indicated to establish the differential diagnosis between carcinoma and ulcer. Since carcinoma makes very slow progress in elderly patients the delay of a few weeks is preferable to the risk of an operation. Even in cases of carcinoma the drug is of beneficial influence as it cures the peritumoral inflammation and superimposed secondary infection which facilitates the gastrectomy. In all so-called surgical ulcers of the vertical portion in elderly patients this treatment should be applied as a last resort before operation is attempted.

No explanation is given for the miraculous success obtained with this new compound.

WERNER M. SCHWITZ, M.D.

Bloech P. Severe Hemorrhages from Gastro-duodenal Ulcer (Le grandi emorragie da ulcera gastro-duodenale). *Polidictica sez. chir.* 1946 53 244.

Blood studies were made on 48 patients with gastric hemorrhage. The authors concluded that for the first 3 or 4 days there is a gradual rise in the azotemia which then gradually begins to return to normal. There is a parallel rise in polypeptidemia, aminoacidemia, and xanthoproteinemias.

The blood chlorides tend to diminish notably in grave cases.

Of the 48 cases studied 3 terminated fatally. All 3 had an abnormal rise in azotemia and death occurred between the ninth and twelfth days. None of these presented an anemic picture or evidence of recent hemorrhage. The azotemia is considered to be of great prognostic significance. The azotemia curve rose to 70 mgm. per cent as an average for all cases. In the 3 cases in which death occurred this figure rose to 615, 500 and 337 respectively.

LECCIA J. FRONZONI, M.D.

Gambigliani Zoccolotti A. and Zambelli E.: Treatment of Gastroduodenal Ulcer with Novocain Given by Mouth (Sulla terapia dell'ulcera gastro-duodenale con novocaina per os). *Minerva med. Tor.*, 1946, 37 493.

Reference is made to the original work of Hamori and Szenes (1943) in the Russian clinic at Budapest on the anesthetic treatment of peptic ulcer when these men substituted novocain for larcocaine as originally used by Bayer.

The method of treatment was as follows:

The novocain was dispensed in 1 gm. powders which the patient was instructed to dissolve in 100 c.c. of water (1% solution). This was taken in about 20 minutes by mouth on an empty stomach. Taking the drug slowly avoids the burning sensation and too rapid emptying from the stomach. The patient lay in a supine position for 30 minutes after which he was allowed to have breakfast. No special diet was

prescribed and no other medication used except an occasional antacid. This was not allowed for several hours after the novocain was taken in order to avoid precipitation of the drug.

The cases treated were 20 in all: 13 gastric ulcers on the lesser curvature, 2 pyloric ulcers and 5 duodenal ulcers. Of the patients with gastric ulcers 2 showed tarry stools of moderate degree. Those with pyloric ulcers showed retention at 12 and 24 hours respectively.

Seventeen cases, or 85 per cent, were improved: 12 gastric, 1 pyloric and 4 duodenal.

The duration of the treatment was from a minimum of 20 days to a maximum of 60 days. No disturbance was noted from the use of the drug.

The beneficial results are explained as being due to the anesthetic action on the ulcer itself which causes a diminution of pain and also of acid secretion of the stomach. Bayer was quoted as stating that the beneficial results are due to the fact that the ulcer area is rendered insensible, as first shown by Spiesse who demonstrated that areas of inflammation heal more readily when locally anesthetized. These results are similar to the beneficial results of the local use of novocain in the treatment of trophic ulcers. Reference is made to good results obtained by dorsal and lumbar sympathetic ganglion blocks, as reported by Mezo and Daskowsky. Froehlich is quoted as reporting 14 cures among 25 cases lasting over 4 years after removal of the first lumbar ganglion on one side. The paper is summarized as follows:

1. The daily administration by mouth of a watery solution of novocain is considered efficacious treatment of peptic ulcer. It is based on a neurocirculatory mechanism.

2. Recent ulcers of the lesser curvature are more easily healed.

3. Ulcers with pyloric stenosis and retention do not respond to this treatment. If however the retention is due to functional spasm results are good.

4. The novocain treatment of ulcers is not intended to take the place of other methods but no peptic ulcer should be considered medically incurable until this valid method is tried.

LUCIAN J. FRONZONI, M.D.

Wangensteen, O. H.: The Role of the Surgeon in the Management of Peptic Ulcer. *England J. Med.*, 1947 236 191.

Wangensteen has estimated that about 10,000 people die yearly in this country from ulcer and its complications. Autopsy records show an ulcer or ulcer scar in from 2 to 5 per cent of the cases.

It has been shown that gastric mucosal erosions occur readily and that in the exteriorized gastric or intestinal mucosal pouch the progress from a mucosal erosion to a fully developed ulcer can take place in the course of a few hours under the influence of dripping gastric juice.

The well known Mann-Williamson experimental procedure for producing ulcer in the dog, although highly unphysiologic in many respects focussed

A successful operation should not compromise the future of the patient and should carry a risk of life that is less than that of the disease. Patients with gastric ulcer are more readily cured of the ulcer diathesis by resection than patients with duodenal ulcer. Women are more amenable to cure by operation than men.

Wangensteen reiterates that on the basis of experimental studies an operation for combating the ulcer diathesis in man consists of an extensive gastric resection (75 per cent) the employment of a short afferent duodenojejunal loop and a retrocolic anastomosis at the suspensory duodenojejunal ligament, and the excision of the antral mucosa. Failure on the part of the surgeon to observe all these elements of a satisfactory resection may invite a stomal ulcer.

ROBERT TURNER, M.D.

Aguirre, C. Postgastrectomy Peptic Ulcer following Billroth I Operation (Ulcers peptica post gastrectomia en el Billroth No 1) *Arch. argent. enferm. ap. digest.* 1946 31 355

The author has observed the incidence of 4 peptic ulcers among 133 cases treated by gastrectomy according to the Billroth No. 1 method. The recurrences started from 8 months to 4 years after the gastrectomy and the 4 patients showed a marked hyperchlorhydria.

The clinicorontogenological examination has made possible the exact diagnosis, and has confirmed the evolution of the process up to distalization following medical management.

Others have found that an achlorhydria resulted in practically all cases of gastric ulcers but in only 25 per cent of cases of duodenal ulcers in which a Billroth No. 1 operation was done. In the author's own series 50 per cent of the patients with gastric ulcer subjected to the Billroth No. 1 operation presented achlorhydria later.

As a prophylaxis against postoperative recurrence of ulcers one must resect the pylorus and have an ample anastomotic opening. Vagotomy is of benefit not only as a prophylaxis against recurrence but also as a treatment for cases which do not respond to medical management.

ARTHUR F. CIPOLLA, M.D.

Eliaeson E. L. and Welty R. F.: A Ten Year Survey of Intestinal Obstruction. *Ann. Surg.* 1947 125 57

A statistical review of 202 cases of intestinal obstruction is presented.

The average age of those who survived was 44 years and of those who died 59 years.

The mortality did not seem to be influenced by whether or not the obstruction was complete or partial, acute or chronic. Improvement in operative technique and in pre and postoperative care probably accounts for this.

The mortality rate in cases of small bowel obstruction was shown to be one half that for cases of large bowel obstruction.

Thirty four per cent of the patients with obstruction due to malignancy and 31 per cent of those with obstruction due to femoral hernia died. This is in contrast to a mortality of 5 per cent in the cases of obstruction which were due to inguinal hernia.

The mortality in the group showing strangulation was only 13 per cent.

If resection was necessary the mortality rate was almost doubled.

The overall mortality in this series was 11 per cent. If the cases of malignancy and strangulation are excluded the mortality in the remaining 159 cases is 1 per cent.

Following the introduction of the Miller Abbott tube the mortality in this series was reduced by one half. Other factors including transfusion chemotherapy and improvement in anesthesia unquestionably contributed to the decrease in mortality.

Oberhelman H. A. and Condon, J. B. Acute Intussusception in Infants and Children; An Analysis of 95 Cases in the Cook County Children's Hospital. *Surg. Clin. A. America* 1947 27 3

The authors present an analysis of 95 cases of acute intussusception in infants and children admitted to the Cook County Children's Hospital, Chicago during the 21 year period from 1925 to 1945 inclusive.

The age incidence was as follows: 68.6 per cent of the patients were under 1 year (of which 60.6 per cent were under 9 months and 36.3 per cent under 6 months); 20.3 per cent were between 1 and 3 years; 9 per cent between 2 and 3 years and 3 per cent were 3 years old or over. The youngest was 2 weeks old and the oldest 15 years. There were 65 males and 30 females. Forty-six patients were white and 45 negro in 4 cases the race was not mentioned. There was no marked seasonal variation. Changes in diet were noted in the histories only occasionally and there was little difference in the incidence of intussusception in the breast fed and the artificially fed babies. One patient swallowed 1/2 ounce of turpentine on the day before the onset.

The following pathologic conditions were found at operation and considered as demonstrable etiologic factors in 16 patients: Meckel's diverticulum in 6, enlarged mesenteric lymph nodes in 3, congenital malformation of the mesocolon in 2, intestinal polyps in 2 (1 in the ileum and 1 in the sigmoid colon), an adhesive band passing over the front of the terminal ileum in 1, a nodule of aberrant pancreatic tissue in the ileum in 1 and a recently invaginated appendical stump in 1.

The onset of symptoms was acute, usually characterized by vomiting and abdominal pain. Vomiting was most frequent occurring in 89 patients. Abdominal pain present in 84 patients usually preceded the vomiting and was cramplike and intermittent in character.

Bloody stools, usually of the currant jelly type were noted in 82 patients. In most instances the

blood did not appear before 12 to 16 hours after the onset of pain.

Abdominal masses were noted in 77 patients, the most frequent sites being the right upper quadrant and the left lower quadrant. The masses were oval, movable as a rule, and moderately tender. Rectal examination was made in 63 patients and, in 13 masses were palpable.

Signs of intestinal obstruction were noted in 40 patients, and in the first 24 hours in 19 of these. Shock was present in 34 patients; in 11 it was an early symptom initiated by the sudden onset of severe pain and vomiting, and in 13 it was associated with signs of intestinal obstruction.

The diagnosis of acute intussusception was correctly made in all but 1 patient. The symptom triad of abdominal pain, vomiting, and bloody stools was present in 67; these patients also had palpable abdominal masses. Roentgen examination, by means of either a scout film or a barium enema, was made in 35 patients.

Operation is advised for cases of acute intussusception because of the uncertainty of complete reduction and the danger of causing overdistention and rupture of an already damaged bowel by hydrostatic pressure. The grouping of patients into nonoperative and operative groups does not mean that the reduction of the intussusception in the nonoperative group was so planned.

In the nonsurgically treated group there were 10 patients, representing 11 cases (1 recurrence). In 6 patients the intussusception was reduced by means of the barium enema which was used as a diagnostic aid. The reduction was spontaneous in 1 case. There were 3 deaths (37.5 per cent mortality), 2 of the patients who died were moribund on admission, and an error in diagnosis was made in the third fatal case.

In the surgically treated group there were 85 patients, representing 88 operations and 16 deaths (18.8 per cent mortality).

Adequate preoperative care is essential. This is represented by the administration of fluids parenterally to overcome dehydration, supplemented by plasma or blood in critically ill patients, and continuous Wangenstein suction through a Levin tube to keep the stomach and upper intestine decompressed. For preoperative medication infants under 1 year received atropine (1/500 gr.) without morphine, and children over 1 year were given atropine (1/550 gr.) and rarely morphine.

Ether is the anesthetic of choice and was used by the open drop method in 70 of the 88 operations.

Intussusception is a migratory lesion, but regardless of its migration it usually takes its origin in the ileocecal region. The operative incision should, therefore, be made in the right lower quadrant of the abdomen. A relatively long right rectus incision permits exploration of the other quadrants.

The types of intussusception were as follows: ileocecal or ileocolic in 64 patients; ileosigmocecal or colic in 8; ileocolic in 4; colocolic in 4, and appendicocolic in 1. The type was not mentioned in 4 patients

and in 3 cases the intussusception was found to be reduced.

The operative procedure was manual reduction in 68 patients, aided in a few instances by hydrostatic or aerostatic pressure. Appendectomy was performed in 7 cases because of acute hyperemia. (The authors do not recommend routine appendectomy.) In 1 patient a polyp of the sigmoid was the apex of a sigmoidorectal intussusception, which had presented itself at the anus. Through an anal speculum the polyp was excised and the intussusception reduced by manual manipulation.

Intestinal resections were performed in 13 patients because the intussusception was either irreducible or the bowel wall was necrotic after reduction. The types of resection were as follows: Lahey-Miles exteriorization in 6 (recommended for resections of the cecum and terminal ileum); resection of the ileum and end-to-end anastomosis in 5; primary resection of the cecum and ileum in 1; and Meckel's diverticulectomy in 1. In 1 patient an anastomosis was made around the irreducible mass.

Adequate postoperative care is highly important. The measures discussed in the preoperative care are continued. Plasma and blood transfusions are especially indicated on the day of operation and again on the third or fourth postoperative day. Postoperative distention must be controlled by continuous suction until evidence of bowel function has returned. At this time fluids and foods may safely be administered orally. Penicillin, the sulfonamides and vitamins are used routinely.

There were 4 recurrences in 3 patients, 3 after barium enemas and 1 after operation. In 1 patient in whom an appendectomy was performed after manual reduction the invaginated appendical stump was found to be the apex of the intussusception. A Meckel's diverticulum was the cause in 1 patient.

Postoperative complications occurred in 9 patients and were as follows: evisceration in 3; bronchopneumonia in 3; wound infections in 2; and intestinal obstruction in 1 patient; all of the patients recovered.

The mortality rate among the 95 patients was 19.1 per cent. Of the 9 patients who died, 2 were moribund on admission and no surgery was considered. The operative deaths occurred during operation in 1 patient, within 30 hours postoperatively from shock in 11 and in less than 5 days from toxemia and generalized peritonitis in 4.

The duration of symptoms is the greatest single factor responsible for the high mortality. The mortality rate rose from a 3 per cent for the first day to 15.7 per cent for the second day and to 40 per cent for the third day.

Signs of intestinal obstruction offered an unfavorable prognosis. Thirteen, or 63 per cent, of the 19 patients who died had visible signs of obstruction. The relation of shock and mortality varied with the duration of the symptoms: 1 death occurred among 17 cases in under 48 hours (5.9 per cent mortality), while 9 deaths occurred among 17 cases in over 48 hours (53 per cent mortality).

Deaths in relation to the types of intussusception were as follows: 12 deaths in 64 cases of ileocecal or ileocolic intussusception (18.7 per cent mortality); 1 death in 8 cases of ileoileocecal or colic intussusception (12.5 per cent mortality); and none in 4 cases of ileoileal and 4 cases of colocolic intussusception.

The distance to which the intussusception had advanced was not determined necessarily by the duration of the symptoms and the mortality bore no constant relationship to the distances to which the intussusception had progressed.

Meckel's diverticulum was a mortality factor as indicated by the fact that 4 of the 6 patients with Meckel's diverticulum required intestinal resection.

There were 8 deaths among 68 patients treated by manual reduction of the intussusception, a mortality rate of 11.8 per cent. Intestinal resection resulted in 6 deaths among 13 patients, a mortality rate of 46.1 per cent. The total surgical mortality rate was 18.2 per cent. There were 3 deaths among the last 45 patients, a mortality rate of 6.6 per cent. Reduction in mortality was due to improved surgical technique and judgment and to advances in preoperative and postoperative care. ERNEST E. ARNHEIM, M.D.

Kay J. H., and Lockwood J. S. Experimental Appendical Peritonitis. The Significance of Imbalance of Circulating Fibrinolytic and Anti-fibrinolytic Factors in the Course of the Disease. *Surgery* 1947 31: 155

The following observations made in a preceding article led to the present study:

1. Appendicitis is of local origin and culminates in an acute toxemia characterized by profound disturbances in the hemodynamic equilibrium and an impaired function of the lungs, liver and vital organs.

2. The systemic character of the disease is reflected by shifts in the concentrations of the normal blood constituents including water, electrolytes, nonprotein nitrogen, total protein, hemoglobin and prothrombin.

3. The outcome of the disease, whether death or survival, appeared to be related to the "condition" of the animal prior to the experiment rather than to any bacteriologic or anatomic variations.

4. Animals handicapped by an abnormal prothrombin time upon entering the crisis of the disease failed to survive, while those with a normal prothrombin time survived. Fluctuations of the prothrombin time tended to co-ordinate in time with fluctuations in the sedimentation rate, whole blood specific gravity and the hematocrit.

The present article is a report of experiments designed to explore the possible relationship between survival from peritonitis and the antiproteolytic activity of the blood. Data of other works reviewed relevant to this study indicate several important points. Intravenous administration of trypsin produces an immediate fall in the blood pressure and a reduction in the amount of circulating fibrinogen possibly by its conversion to fibrin. Prolonged shock produces a similar change. A proteo-

lytic enzyme occurs normally in human serum and is probably related to the normal clotting mechanism. And finally repeated injections of trypsin in rabbits increased the antiprotease activity of the serum.

Experimental peritonitis was produced in 128 dogs and the fibrinolytic and antifibrinolytic factors in relation to the survival were studied in 37 of the group. The fibrinolytic activity of the blood was studied by two methods. First, by simple incubation of recalcified oxalated dog plasma at 37° C. to determine whether spontaneous lysis of the dogs own fibrin occurred within a period of 48 hours. Second dog serum treated with chloroform to remove at least a portion of the nonspecific inhibitor of proteolytic enzyme was added to a standard preparation of bovine fibrinogen. This method the author considered was more a measure of the amount of proteolytic enzyme inhibitor than a measure of the amount of enzyme. The results of the experiments were as follows:

1. Spontaneous lysis of plasma fibrinogen and fibrin occurred in much greater frequency in the animals that died than in those which survived. Lysis invariably occurred in samples drawn within 12 hours preceding death.

2. Sharp fluctuations in available fibrinogen nitrogen were observed during the disease in all of the animals but there was not a clear correlation between the fibrinogen nitrogen levels and the activity of fibrinolytic factors. The animals surviving showed fibrinogen nitrogen levels which were approximately 65 per cent greater than the preoperative values.

3. The fibrinolytic activity of chloroform treated serum was significantly higher in dogs which died than it was in dogs which survived.

4. The preoperative administration of trypsin in amounts sufficient to build up the antiproteolytic activity of the serum had a marked effect upon survival—only 1 of the 15 animals treated with it died. Of the control animals, 41.7 per cent died.

5. Neither penicillin nor heparin were of therapeutic value in the small group treated therewith.

FREDERICK C. HOBAN, M.D.

Miller E. M.: Bowel Obstruction in the Newborn. *Surg Clin N America* 1947 27: 73

The author presents a brief review of the clinical and pathologic features and the surgical treatment of congenital obstructions, mainly atresias, of the esophagus, duodenum, ileum and rectum.

A report of the results of treatment in the author's clinic is limited to congenital obstructions of the duodenum and ileum. There were 7 cures in 11 cases of duodenal obstruction, the number of cases with intrinsic obstruction (atresia) or extrinsic obstruction (incomplete rotation of the colon) is not stated. An antecolic duodenojejunostomy is advised for atresia or stenosis of the duodenum. Two successful results in atresia of the ileum are mentioned, the operative procedures being a side-to-side ileocolostomy and a temporary ileostomy in the proximal loop in both cases. ERNEST E. ARNHEIM, M.D.

Devine, J.: A Concept of Paralytic Ileus; A Clinical Study. *Brit. J. Surg.* 1946, 34: 158.

A review of the literature regarding intestinal obstruction with especial regard to paralytic ileus and intestinal physiology is presented. True or idiopathic postoperative paralytic ileus is rare.

Investigations were made and the following effects on small bowel motility in paralytic ileus were noted:

- 1 Heat and turpentine stupes on the abdomen had no effect on bowel movements.
- 2 Luminal decreased the peristalsis and tone
- 3 Penicillin and sulfonamides did not materially affect the peristalsis.

4. Overdistension of the stomach caused loss of tone and decreased movement of the small intestine.

5. Stimulation of the colon, as by enemas, caused activity of the small intestine.

Postoperative infection is the most frequent cause of postoperative ileus. Three phases of ileus are postulated:

1 Stage 1 in which the movements are active, co-ordinated, responsive to stimulation, and effective

2 Stage 2 in which the movements become irregular, inco-ordinated, and ineffective

3 Stage 3 in which intestinal mobility ceases. Stimulation of the intestine during stage 3 may promote the development of paralytic ileus.

Therapy should consist of prophylaxis by eliminating preoperative cathartics by gentle operative manipulation of the intestine and avoidance of peritoneal contamination; restriction of oral fluids in the immediate postoperative period; minimal use of atropine and barbiturates postoperatively; and no stimulation of the small intestine by enemas or drugs during the period when intestinal movements are irregular, unco-ordinated or absent. Morphine should be used during these periods. When fully developed ileus is present the prompt use of intestinal intubation, intravenous plasma, and fluids necessary to maintain the proper electrolytic balance are urged. If it is impossible to insert an intestinal tube in a patient during a fully developed ileus the author suggests a high jejunostomy and intubation.

The following outline of paralytic ileus is reproduced directly from the author's paper:

- I Intra-abdominal
 - A. Peritoneal irritation
 - 1 Traumatic
 - a. Postoperative
 - b. Penetrating wounds
 - 2 Bacterial peritonitis
 - 3 Chemical
 - a. Extravasation of blood
 - b. Perforated peptic ulcer
 - c. Bile peritonitis
 - d. Acute pancreatitis
 - B Vascular changes
 - 1 Strangulation
 - a. Intramural distension following mechanical ileus

- b Extramural Compression of the mesenteric vessels
 - 1 Mesenteric thrombosis
- C Extraperitoneal irritation
 - 1 Hemorrhage
 - 2 Infection
 - 3 Renal
- II Extra-abdominal
 - Toxic
 - 1 Pneumonia
 - 2 Uremia
 - 3 Empyema
 - 4 Systemic infection
 - B Neurogenic
 - 1 Injuries and diseases of the spinal cord
 - 2 Lead poisoning
 - 3 Fracture of the lower ribs

C. FARMER, KITTLE, M.D.

Mason, J. M. III, and Linn, J.: Lipomas of the Colon. *South. Surgeon*, 1947, 3: 128

Lipomas are found throughout the intestinal tract. They may be subserous or submucous; the latter are considered true lipomas. They may be asymptomatic when small or they may cause symptoms. When symptoms are present they are often due to varying degrees of intussusception. Preparation of the colon with succinylsulfathiazole followed by resection and primary end-to-end aseptic anastomosis with use of the Stone intestinal clamps is a satisfactory method of treatment. This technique when feasible, presents obvious advantages over the two-stage exteriorization type which requires more prolonged hospitalization and operation for secondary closure.

In a recent article on surgery of the colon one of the authors advocated that an aseptic primary end-to-end anastomosis be performed with the use of the Stone clamps in elective, nonobstructive prepared cases when resection of the large intestine is indicated.

They report a case of submucous lipoma of the splenic flexure of the colon. The technique of such an anastomosis is described. HARRIS, W. FIXX, M.D.

Santý P., Dargent M. and Mllehaudi: Résultats de Chirurgie Préservant le Sphincter F. netion in Cancer of the Rectum (Résultats de la chirurgie conservatrice de la fonction sphinctérienne pour cancer du rectum). *Lyon chir.* 946 4: 641

In France there has been a definite trend toward the treatment of cancer of the rectum by conservative surgery and contact irradiation rather than by mutilative surgery and colectomy.

Preservation of the sphincter has been accomplished by two methods: sacral amputation and sacral resection. In the former all of the anal mucosa is removed and the sigmoid is pulled through the sphincteric ring which alone is preserved. In sacral resection a segment of the lower mucosa is preserved and continuity is re-established by end-to-end suture.

Of 90 patients treated by conservative surgery 76 could be followed up. Fifty-one patients were treated by amputation and 25 by resection. The mortality for all types of conservative surgery was 7.7 per cent, the recurrence rate was 6.6 per cent, and the incidence of postoperative metastases was 12.2 per cent. Of the survivors 41.1 per cent had a good functional result, 3.3 per cent had a poor functional result, and 55.6 per cent had a mediocre functional result.

The rectal tumor was located in the ampulla in 47 cases. Thirty-seven of this group were treated by sacral amputation and 10 by sacral resection. Of the former 23 were followed up for a long period and the results were as follows: 15 good, 2 poor, and 6 mediocre. Of the latter 1 presented poor results and 7 presented mediocre results. Thus for ampullary carcinoma the results of resection were inferior to those of amputation.

The rectal tumor was located in the rectosigmoid area in 29 patients. Fifteen were treated by resection and 14 by amputation. Of the 15 resections 11 could be followed up. Seven results were perfect and 4 were mediocre. Of the 14 amputations 13 could be followed up. In 7 the results were excellent and in 6 further treatment was required. Thus, for rectosigmoid carcinoma, the results of resection were better.

To compare these results with those of radical surgery the authors refer to 41 cases reviewed by Bozon and treated by the operation of Lockhart Mummery. Nineteen of these could be followed up for more than 5 years. The mortality was 7.31 per cent or essentially the same as for the conservative group. Seven or 36.8 per cent had no recurrence. Of the conservative group 34 were followed for more than 5 years. Twelve or 50 per cent of the patients survived.

As a basis for comparison of their results with those of contact irradiation therapy the authors cite 28 cases reviewed by Lamarque. Twenty-four patients survived. Eight of the latter were re-examined at the end of 3 years and biopsy showed no evidence of recurrence.

EDWARD W. CIBER, M.D.

Rachet J., and Rey M: Treatment of Cancer of the Anus (Le traitement du cancer de l'anus). *Rev. chir. Par.*, 1946 65 257.

Treatment of cancer of the anus has passed through two stages: one is purely surgical, when the condition is associated with cancer of the rectum and its radiosensitivity is unknown, and the other is almost exclusively one of radium therapy. This explains the dearth of recent surgical statistics. In consideration of the painful sequelae of radium therapy the question as to whether this method is to be recommended for cancer of the anus has been brought up for discussion. Only eminent radiotherapeutists have expressed themselves but no surgeons.

Following a discussion of the advantages and disadvantages of surgical and radium therapy the au-

thors conclude that radium therapy constitutes the most simple method of treatment. Statistically it has not been possible to demonstrate the superiority of either method. The number of cures obtained by the two methods seem about equal. Unfortunately the accepted surgical technique in these cases leaves the patient with the great inconvenience of an artificial anus. Radium therapy spares the patient this burden but is usually associated with severe and painful sequelae. These unfortunate sequelae have been attributed by the radiotherapeutists to the fact that patients have been referred for treatment at too late a stage of the disease, to faulty technique, faulty indications, and the use of excessive doses. Roux Berger and his co-workers have suggested the following course of procedure: always begin with physiotherapeutic therapy and if this fails proceed after 2 or 3 months to surgical intervention.

The authors remain skeptical toward this proposal, believing that if surgery has been found dangerous after certain radiotherapeutic procedures such as radium puncture it will surely prove even more dangerous in these late painful complications with the associated fibrous changes. If it were possible to foretell at an earlier stage that transitory painful reactions would persist and grow worse, surgery might prove helpful. However the course of these complications cannot be foreseen even by the most experienced specialists. It is to be hoped that new techniques and discoveries may be able to prevent these unfortunate sequelae of radium therapy.

Neither surgery nor radium therapy can be considered as having been fairly tested until large series of cases in earlier stages of the disease have been treated by the two methods. Biopsy should be done in all abnormal lesions of the anus associated with induration and failure to heal promptly.

EDITH SCHANCKE MOORE, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Riopelle, J. L.: The Elastic Tissue of the Gall Bladder. Anatomic, Clinical, Radiologic, and Pathogenic Considerations of a Previously Neglected Lesion of the Gall Bladder (L'élastose du cholesty: Considérations anatomiques, cliniques, radiologiques et pathogéniques sur une lésion jusqu'ici négligée, de la vésicule biliaire). *Union Méd. Canada* 1946 75 1486.

Pathologists have devoted very little attention to the elastic fibers in the wall of the gall bladder. By selective staining of gall bladder specimens one may note considerable variation in the elastic elements of the wall. Usually the elastic tissue is present in limited amounts and predominates at the level of the tunica muscularis in the form of layers or multiple tracts. By more careful search it may also be demonstrated in the connective tissue of the chorion and especially of the adventitia, and even in the serosa. More rarely elastic tissue predominates in the adventitia itself.

The author believes that the presence of these elastic fibers is not a mere anatomical curiosity, but that a study of them clarifies certain aspects of the pathogenesis of cholecystitis. He has reviewed 595 cases of cholecystitis and cholelithiasis and has examined 575 gall bladder specimens. These specimens were sectioned longitudinally as soon as excised and before fixation. Stretching of the specimen was avoided. Positive identification of elastic tissue was obtained by selective staining and was found in 20 specimens. One additional specimen was added to bring the total number of specimens to 30.

In its relation to the musculature, in its configuration and in its texture, the elastic tissue of the gall bladder wall presents the characteristics of a new growth rather than of a simple degenerative lesion. The production of elastine in the adventitia is constantly associated with a variable excess of the same substance either in the musculature or in the connective tissue commonly associated with cholecystitis and cholelithiasis.

The clinical picture of the patients whose gall bladders contained an excess of elastic tissue was characterized less by severity of painful phenomena and more by vague indigestion and reflex phenomena. The duration of symptoms is somewhat longer in this group than in the group with cholecystitis in general, the mean being 7.5 years as compared with 3.8 years. Cholecystography usually reveals a poorly visualizing or nonvisualizing gall bladder. Stones may or may not be present.

The pathogenesis of this elastic tissue is obscure. Senile dystrophy is an unlikely hypothesis and post-inflammatory regeneration theories do not agree with many accepted facts. The author is inclined to favor a mechanical disturbance of the vesicle function requiring a process of adaptation of the gall bladder wall as the chief pathogenic factor.

EDWARD W. GIBBS, M.D.

Santy P.: Drainage in Cholecholestomy for Lithiasis (Le drainage dans la cholécholestomie pour lithase). *Rev. chir. Par.* 1947, 66.

The author analyzes the results of external biliary drainage for the treatment of common duct stone in 183 cases treated in a 30 year period. The first 96 cases were reviewed in 1936 by Aufrère. Although the mortality was 9.6 per cent for the entire group it was reduced to 5.7 per cent for the last 87 cases.

For convenience of discussion the patients have been classified into four groups.

In the first group are included 86 patients who exhibited the classical picture of common duct stone with intermittent crises of pain in the right hypochondrium or epigastrium, fever and icterus. The total mortality in this group was 8.5 per cent.

The second group comprises 28 patients with atypical symptoms in which the characteristic history was lacking; the mortality was 7 per cent.

In the third group are 32 patients with chronic icterus due to retention often produced by a single stone. The mortality was 9 per cent in this group.

The fourth group of 34 patients presented the most severe syndrome of calculous angiocholitis. The mortality in the first 19 cases of this group was 36 per cent but recent advances in preoperative care, particularly vitamin K therapy simplification of the operation and the use of local anesthesia, resulted in a mortality of 6 per cent in the last 15 cases.

The original operation of Kehr was a serious operation performed on enfeebled patients. It carried a high mortality rate. Modification of the operative procedure has simplified it. A right subcostal incision is made only as long as necessary. The liver is not disturbed. The cholecystectomy may be simplified by mere obliteration of the mucosa with the diathermic bistoury.

Exploration of the common duct by palpation and inspection is not adequate in many cases. The author prefers the method of Mallet-Guy to examine the duct by roentgenography with an opaque medium to outline the biliary tree at the time of operation.

External drainage of the common duct should be done with a catheter of fine caliber carefully placed with minute sutures and well peritonized. It is usually removed between the twelfth and twentieth days after the patency of the duct has been confirmed by clamping the tube, and also by roentgenographic and manometric studies. EDWARD W. GIBBS, M.D.

Mallet-Guy P. and Gautier R.: Physiopathologie Study of Recurrences following Cholecystectomy (Etude physiopathologique des récidives après cholécystectomie). *Lyon chir.* 1946, 41, 513.

It is difficult to determine by clinical examination and even by operative inspection the cause of recurrent pain and jaundice after cholecystectomy. However by manometric and roentgenographic study of the extrahepatic biliary ducts during operation one may establish a definite cause for recurrence.

Twenty cases with recurrent symptoms following operation are reviewed. In 6 of these an anatomical cause for symptoms was found. Two patients had calculi in the biliary ducts; 2 had pancreatitis, 1 patient had a tumor of the papilla of Vater and 1 had an operative injury to the ducts. In 14 patients the recurrent symptoms were found to be on a functional basis. Ten patients had hypertony of the sphincter of Oddi and 4 had atony of the sphincter.

The case histories of these patients are reviewed and the intrabiliary pressure curves and roentgenographic patterns made during operation are illustrated and correlated with the anatomic or functional factors responsible for recurrence of the symptoms.

The authors conclude that the majority of these factors exist at the time of the first operation and urge the operator to determine at that time the intrabiliary pressure curve and roentgenographic pattern of the ducts in order that he may institute the proper treatment and prevent the development of recurrences.

EDWARD W. GIBBS, M.D.

Baravalle N: The Pancreatic Syndrome during the Immediate Postoperative Period (Sindromes pancreáticos en el postoperatorio inmediato de la cirugía biliar) *Archiv Roaario* 1946 11 247

Among 400 operations on the biliary system the author encountered 21 cases which were complicated by a postoperative pancreatitis.

Postoperative retention of the pancreatic secretion which occurs not infrequently following cholecystectomy may be demonstrated by the determination of amylase in the urine. In 5 patients the author was able to show the presence of amylase and also bilirubin in the urine after operation. Such observations point to an obstruction of the pancreatic and biliary ducts of a functional or inflammatory origin. Postoperative pancreatitis may cause tachycardia, profuse perspiration, cyanosis, oliguria (due to peripheral vascular collapse), fall of the arterial pressure, pain in the operative region, intestinal paralysis, subnormal or slightly elevated temperature, diminished alkaline reserve and increased hemocoagulation.

Three types of postoperative pancreatitis may be distinguished: (1) the attenuated form characterized chiefly by tachycardia, slight hypotension, oliguria, and the presence of amylase in the urine; (2) the type characterized by a peripheral vascular collapse, in which the pulse frequency may reach 140, the blood pressure falls more and more, cyanosis appears, and typical postoperative shock makes its appearance; and (3) the peritoneal form, characterized by a slight elevation of the temperature, the appearance of amylase in the urine, and symptoms of peritonitis which dominate the picture. The type of anesthesia employed during the operation does not seem to be an important factor. Cholangiography employed in the course of the operation can not be blamed because pancreatitis may develop in patients in whom this method has not been employed. Operative maneuvers such as the insertion of probes into the common duct may be an important factor. Morphine should not be employed preoperatively or postoperatively, because it causes a contraction of the sphincter of Oddi, thus facilitating stasis.

Differential diagnosis must be made from hepatic insufficiency, biliary peritonitis, and operative shock caused by hemorrhage.

As stated, morphine should not be employed before the operation or it should be combined with atropine. Barbiturates are preferable to morphine. The emotional condition of the patient deserves attention because it may affect the sphincter of Oddi. To diminish the reflexes, the author supplements general or spinal anesthesia with injections of novocaine into the abdominal wall and subserosa of the gall bladder. Extreme care should be exercised in exploring the common duct, especially its retroduodenal portion. If the duct is flushed with saline solution, no great pressure should be exerted.

Blood transfusion is indicated in the more severe types of postoperative pancreatitis. Atropine should

be given to relax the sphincter. Ephedrine is very valuable to combat collapse. This drug, as well as atropine, diminishes the pancreatic secretion. Large doses of polyvalent antipangreous serum should be administered. As a rule the prognosis is favorable. JOSEPH K. KARAT, M.D.

Mallet-Guy P, Marion P, and Jeanjean R.: Indications and Results of Left Pancreatectomy for Lithiasis of the Duct of Wirsung (Indications et résultats de la pancréatectomie gauche dans la lithiase du canal de Wirsung) *Lyon chir* 1946 41 661

The surgical treatment for lithiasis of the duct of Wirsung is classically represented by pancreatectomy with extraction of the stone followed by drainage. This procedure carries with it the risk of fistula formation, recurrence, and aggravation of an associated lesion.

The authors review 3 cases in which a left pancreatectomy for lithiasis of the duct of Wirsung was followed by very satisfactory results.

The first patient had 2 stones in the duct, one in the region of the head of the pancreas and the other in the left portion of the body. There was a associated chronic pancreatitis and thrombosis of the splenic vein. A pancreatectomy at two sites in the duct of Wirsung seemed illogical and would seem to offer little improvement for the chronic pancreatitis and venous thrombosis. Hence, all of the lesion to the left of the midline was eliminated by a left pancreatectomy and splenectomy, and the stone in the duct near the head of the pancreas was removed by pancreatectomy. The result has been excellent for 27 months.

The second patient had a right and left pancreatectomy for the removal of calculi, but a recurrence necessitated reoperation 15 months later. At that time an abscess of the left portion of the pancreas was found and a left pancreatectomy was done. This patient was in excellent condition 6 months later.

The third patient with lithiasis of the duct of Wirsung was treated primarily by left pancreatectomy and has made satisfactory progress for 6 months since operation.

Stones in the midportion of the duct of Wirsung produce lesions of chronic pancreatitis in the left half of the pancreas, lesions which simple removal of the stone does not cure. It is the removal of this portion of the pancreas which produces an alleviation of symptoms, even though pancreatectomy may also be necessary for removal of the stone in a more cephalic portion of the gland.

EDWARD W. GIBBS, M.D.

Ballico G: Sarcoma of the Spleen (I sarcomi della milza) *Gior Ital chi* 1946 2 481

The number of cases of sarcoma of the spleen reported and the small number of pages dedicated to the subject in texts motivated the author to report his case.

The percentage of primary tumors of the spleen as compared to all types of tumors has been re-

ported as 65 per cent or 6 cases in 6,500 autopsies. Of these 6 primary tumors of the spleen, 3 were benign (angiomas) and 4 malignant (sarcomas). Carcinoma of the spleen is considered very rare and, when it occurs, is attributed to epithelial cell rests or the inclusion of pancreatic tissue in the parenchyma of the spleen.

In the history it was noted that the patient complained of upper left quadrant pain for the past year. It had been worse during the past 3 months and was accompanied by mild fever. A large palpable tumor was present in the upper left quadrant, extending to the midline and down to the iliac crest. Liver dullness was within normal range.

The urine showed traces of albumin and mucopus, a few hyaline casts, numerous pus cells, and numerous epithelial cells. The hemoglobin was 63 per cent, the red blood count 3,300,000 and the white blood count 10,200.

The diagnosis of sarcoma of the spleen was based on the location of the tumor, age, rapid weight loss, blood picture, and elevated temperature.

A diagnosis of hydronephrosis was made by a consultant called in to see the patient. A descending pyelogram failed to reveal any dye on the left side, but demonstrated a mild hydronephrosis on the right side. A retrograde pyelogram revealed the left kidney to be on the right side and low. This finding was considered to be congenital in nature rather than caused by displacement by the large mass. From these studies hydronephrosis was excluded.

The patient was submitted to an exploratory laparotomy under ether anesthesia, after a transverse incision. An enlarged spleen was found and during the exploration the capsule was torn which permitted the operator to remove some tissue for biopsy study. The tumor was not removable and the abdomen was closed.

The postoperative course was uneventful for 5 days, but then the patient suddenly became gravely ill. She was taken back to her home where she died on the following day. Autopsy was not performed.

The biopsy showed a histological picture consistent with a diagnosis of reticulosarcoma of the spleen. A minute description of the histological picture was given. Reference is made to Oberling's classification of reticulosarcoma, which divides it into differentiated and undifferentiated types, and defines reticuloendothelial sarcoma, reticulomyelosarcoma, and reticulolymphosarcoma, depending upon the evolution of the reticular elements from endothelial, myeloid or lymphatic structure.

MISCELLANEOUS

Imes, P. R.: Abdominal Trauma. *Am J S* 5: 1947 73: 99.

The degree of shock in abdominal trauma is in direct ratio to the extent of the injury represented by the number of viscera involved. Although shock remains the most important factor in the mortality

following abdominal trauma, the recognition of its importance and the emphasis placed on resuscitation in World War II were largely responsible for the improved results. The factors of wounding agent, time lag, the principal viscera involved, and the technical procedures employed appear relatively unimportant. Chemotherapy appears to have favorably influenced the factor of infection in the mortality.

CHARLES BARON, M.D.

Šipek, O.: Abdominal Actinomycosis Treated with Penicillin (Břháal aktinomykosa léčena penikilínem). *Lék listy* 94b, 335.

Two cases of chronic abdominal actinomycosis were treated with penicillin with favorable results. The first case reported was that of a 33 year old woman who had fallen ill suddenly a year previously. The condition was diagnosed as a parametrial abscess on the left side. This was punctured several times and finally drained into the vagina. The drainage tract remained widely open and the process spread rapidly into the lower abdomen and up toward the left kidney. A huge abscess formed and was opened just above Poupart's ligament on the left side. Both drainage tracts were now discharging pus as fistulas; the patient was very much emaciated and so weak that she could not sit up or turn in bed. The condition was considered hopeless and penicillin (15,000 units per 3 hours, for 3 weeks, up to a total of 345 million units) was administered. At the end of this period of treatment the fistulas, including one over the kidney region, had healed; the eosinophils had dropped to 2 per cent; the tissue infiltrations were not confined to the pelvis and the patient had regained her appetite and was able to walk about. A month later she had gained 90 lb in weight and begun to menstruate. She was discharged as cured and has remained so to the present time.

The second case was that of a 37 year old woman who had been operated upon for gangrenous appendicitis a year previously and was now suffering from a large adnexal mass which had perforated into the bladder. A discharging fistula remained in the operation scar and a few weeks later another fistula formed in the old appendical scar. A fluctuating mass had to be incised in the right epigastric region. The pus from this abscess yielded gram positive cocci, bacilli, and the filamentous form of actinomycosis. The condition of the patient became steadily worse; resisted all treatment, and recourse was finally made to penicillin given intramuscularly in 3 hour doses of 15,000 units for a period of 3 weeks. Under this treatment all the fistulas except 1 healed; this continued to secrete sterile pus. Pain ceased, the patient's appetite returned, and she began to walk about. Six weeks later however the condition of the patient suddenly became worse and an abscess formed at the right costovertebral angle and left a wide fistula which discharged fecal material. Penicillin was given by enema, intramuscularly (200,000 units daily for 14 days) and by daily instillations into the abscess cavity (1/3,000 solution). Again

there was dramatic subjective and objective improvement although the fistula from the incised abscess in the back did not close. Three weeks later a third course of penicillin was given. The patient again improved and at present has no pain, temperature, or other symptom. She is stronger, has an appetite, and can get about. There are still 2 small fistulas secreting small amounts of material.

The author ascribes the torpid response of this last case to the devitalized matter which could not be removed from deep in the intestines. The mixed infection present, the weakened condition of the patient before the diagnosis was established, or possibly the acquisition of the actinomycotic organism with penicillin resistance.

JOHN W. BRECKMAN, M.D.

Singleton, A. O.: Surgical Wounds of the Abdominal Wall with Their Favorable and Unfavorable Results. *Am J Surg* 1947 73 333

The author states that surgical incisions in the abdomen, made without regard for the anatomical structure involved, may be truly traumatic wounds. The old well established vertical incisions, particularly in the upper abdomen, are anatomical difficult of closure and hazardous to the patient. Incisions made with the proper regard for the cleavage of the tissues of the abdominal wall, both muscles and fascia, contribute to the comfort and safety of the patient. Such anatomical incisions can be made in proximity to the condition involved, thus insuring greater ease and accuracy in the operation, in addition to leaving wounds that are closed without tension and with a greater security to the patient post-operatively.

CHARLES BARON, M.D.

Allert, F.: *Ascariasis in Surgery* (Sull ascarioidi in chirurgia). *Polidinica scz. prat.* 1946 53 1155

Ascaris lumbricoides is one of the most common parasites in the human intestinal tract. Other forms of *ascaris* found are *ascaris texana* and *ascaris maritima*. The latter are found only rarely. A description of the worm and its development is given. The question of an intermediate host is raised and Stewart is said to believe it is the mouse *Mus musculus* that is responsible. Most authors however do not believe that the intermediate host is necessary.

Ascariasis is found in any part of the globe, most frequently in tropical and subtropical countries and in negroes. According to Soares Hungria 90 per cent of the population in Brazil is affected. In Italy it is most frequent among children in the country, probably because of their playing in the dirt. It is also found in the adult and in the cities. It is rare in children under 1 year of age and in the aged. The most common site is the small intestine where it is found in small but sometimes large numbers. As many as 1,000 worms have been found in a patient with obstruction. They are sometimes found in the biliary and pancreatic ducts. A case is cited in which a cavity in the liver as large as an orange was found.

Appendicitis has been reported as being caused by the worms, especially in children. The presence of

ascariides in the peritoneal cavity has been reported but the pathogenesis is not clear. It may be due to actual perforation or else secondary infection following abrasions in the mucosa. The possibility of secondary invasion following perforation due to other causes must also be considered.

The most common complication caused is intestinal obstruction. This is usually caused by a large number of worms. In some cases, it may be caused by spasm produced by irritant secretions. The most common site is the distal end of the small bowel. The grouping of the worms into a large mass is said to be due to excessive peristalsis induced by action of the worms or their secretions, or to purgatives or drugs used for treatment. The mass may also cause a volvulus or intussusception of the involved bowel.

The symptoms of obstruction are intermittent pain, distention, failure to have bowel movement or the expulsion of gas, hiccups, vomiting, a rapid thready pulse, and a palpable sausage-like mass. The complete obstruction is usually preceded by signs of incomplete obstruction for several days, which gradually progress. A rapid onset of symptoms should lead one to suspect volvulus.

The author describes 4 cases in which he has personally operated. In the first one the small bowel was opened and the worms were removed. The opening was closed with two layers of catgut. In the remaining 3 cases however the mass was broken up and moved on into the cecum by manipulation. This was followed by the administration of *santonina* in the usual dosage on the following day with good results. A complementary appendectomy was performed in 3 cases. In 2 cases there was a torsion of 180 degrees of the involved loop but no disturbance in the circulation. In no case was the diagnosis made before operation. Two cases were diagnosed as obstruction and 2 as appendicitis.

The author advocates this form of treatment when the viability of the bowel is not compromised rather than enterostomy for actual removal of the worms. Complementary appendectomy is also advocated.

Reference is made to authors who advocate medical management of these cases with purgatives and anthelmintics. The author believes that this might be practiced in cases of incomplete obstruction but should never be done when the obstruction might be complete.

LOUCIAN J. FRONZONI, M.D.

Yódice, A.: Postoperative Adhesions (Adherencias post-operatorias). *Rev As med argent* 1946 60 911

Although spontaneous adhesions are formed by a proliferative process in which the reticuloendothelial system plays a part, other factors such as microbic toxins, and irritation of the peritoneum by surgical intervention (including the insertion of drainage tubes, handling of the mesentery and the placing of compresses especially when they are too hot) are etiological agents. Dust in the operating room, powder from gloves, and foreign bodies introduced during the operation must also be included as causes.

The symptoms produced are not primarily related to the adhesions themselves but to the intestinal obstruction which they produce. This obstruction, which in the majority of cases is of a chronic type, results in pain that starts in the area of the incision and radiates to all parts of the abdomen. Audible bowel sounds accompany the pain, and are relieved either by the expulsion of gases or by defecation. X rays show a delayed emptying time or a segmental dilatation of the intestine. Although the extent of the adhesions is in direct proportion to the magnitude of the operation, the adhesions usually appear one year following surgery. The fact that the type of pain occurring postoperatively is the same as was present preoperatively may be explained by the fact that acute appendicitis produces adhesions which give rise to pain; however, on removal of the appendix more adhesions form which give rise to pain that is worse than that experienced before the operation.

The following recommendations to prevent adhesions are given:

1. Spinal anesthesia should be used to relax the viscera.
2. The peritoneum must be handled carefully.
3. Compresses should be used only when there is a possibility of spread of infection to other parts of the abdomen. When they are used they should be

dipped in saline solution not more than from 22° to 30° C. in temperature.

4. The abdominal cavity should be cleansed with low pressure suction.

5. There must be no dust in the operating room.

6. The operator's gloves should be washed to remove powder.

7. Vessels inside of the peritoneal cavity should be ligated.

8. Closure of the abdominal wall from the xiphoid to the umbilicus should be accomplished with fewer sutures and the aponeurosis of the rectus should be only loosely approximated. The use of stainless steel wire in sizes of 30, 32, and 35 is advocated. In the closure of the linea alba, the sutures should be $\frac{3}{4}$ cm. apart. In paramedial closure the suture should include the peritoneum and the posterior and anterior aponeurosis of the rectus.

9. In combating infection, only a solution of sulfa at a pH of 7 should be used, as sulfa powder produces adhesions.

10. A solution of papain gives the best results in preventing adhesions, while sterile liquid vaseline, sterile olive oil, collubiazol and the surgical solution of prontosil, stopton, and daganan are not advocated.

1. The use of heparin is dangerous.

ARTHUR F. CIRIELLO, M.D.

GYNECOLOGY

UTERUS

Ahlborg G. On Conservative Myomectomy. *Acta obst. gyna. scand.* 1946 26 Supp. 6

In an extensive and detailed monograph the author first presents a careful analysis of the literature devoted to myomectomy. This examination shows essentially that no conclusive proof has been presented of the relative advantages and disadvantages of myomectomy as compared to the more radical hysterectomy for the treatment of uterine fibroids.

The author then records in an equally meticulous exposition the primary and secondary results of his own material which comprises 283 abdominal and 46 vaginal myomectomies performed between 1923 and 1941 at the Upsala University Hospital and the Stockholm General Maternity Hospital. 572 hysterectomies for fibroids performed within the same period, are included for comparison. All operations were done under the direction of the same principal surgeon. The methods of preoperative and postoperative care, and the technique of the operations are presented.

Ninety six per cent of the patients subjected to myomectomy were questioned and re-examined a mean period of 6.63 years after operation. Of these 78 per cent were completely symptomless, 19 per cent presented various complaints such as pain and menorrhagia, but were not seriously impeded in their activities and 3 per cent underwent radical operation for recurrence.

Of 93 patients who were subjected to enucleation of one or more fibroids and were in a position to conceive after undergoing operation, 39 (51 per cent) actually became pregnant. 31 of these maintained pregnancy to term or had slightly premature deliveries. The average age of the 8 women who suffered miscarriage was 38.1 years, an age when, the author points out, the risk of miscarriage is ordinarily high. On the whole the course pursued in the pregnancies was normal. During the period of observation, the women concerned gave birth to 34 children. All patients survived. One of the infants whose birth was quite premature, died. Of 24 women experiencing their first delivery after enucleation 14 were primiparas. Of these 9 had spontaneous deliveries, 1 was delivered by cesarean section and 4 were delivered by forceps. Of the 10 women who had previously given birth to children at least once before operation 8 were delivered spontaneously and 2 by forceps. In none of the cases of pregnancy was there a threat of rupture of the uterus.

The author believes that certain of these cases help to clarify the possible influence of uterine fibroids on sterility. In the cases of 5 patients, sterility had persisted from 3 to 15 years before they submitted to myomectomy. The tubes and ovaries as seen at operation were normal. All these patients

became pregnant within a year of the operation. The author concludes that in all probability sterility was cured as a result of the myomectomies.

The conclusions drawn from a survey of the literature and the author's series of cases are presented. The uterus should as far as possible, be left intact during the reproductive period. On the whole, the advantages of a conservative operative approach to fibroids giving rise to symptoms outweigh the disadvantages. In other words preservation of the uterus with retention of the frequently resulting ability to conceive and menstruate outweighs the threat of recurrence and the possible persistence of symptoms. Conversely a radical operation for fibroids will almost always result in a complete cure of symptoms, but the uterus will be sacrificed. The choice between the two modes of procedure must be individualized by reference to the patient's personal history, her social situation and individual preferences, her obstetrical history and other factors. In the presence of sterility it may sometimes prove justifiable to enucleate myomas which are otherwise symptomless. L. JAMES TALBOT M.D.

Blanchi P.: Therapeutic Possibilities in Cancer of the Uterus in Young Women (Sulle possibilità terapeutiche del cancro uterino giovanile). *Rev. ostet. gina.* 1946 1 113.

Eighty-seven cases of uterine cancer in women under 35 years of age are reviewed statistically. These patients came to treatment at the obstetrical and gynecological clinic in Florence, Italy. All of the tumors were primary in the uterus, 76 were located in the cervix and 11 in the body of the uterus. Of the 76 cervical cancers, 27 were in the first and second groups of Schmitz' classification, and of these 15 were treated by hysterectomy alone, 10 were irradiated and 2 were treated by hysterectomy but the operation preceded or followed irradiation therapy. Five year survivals occurred in 7 (83.3%) 6 (85.7%) and 2 (100%) cases, respectively.

Forty-two patients were classified as belonging in the third group of Schmitz' classification and of these, 8 were operated upon, 16 were irradiated, and 7 were treated by the combined method. The respective 5 year survivals were 0 (0 per cent) 20 (28.5 per cent) and 1 (20 per cent). In addition, 1 of these patients was treated only medically and died within a year. There were 7 inoperable cases in the fourth group of this classification, 2 of these were given irradiation treatment and 5 medical. There were no 5 year survivals. These percentages are based on only 18 patients in the first group, 31 in the second, and 6 in the third (Schmitz' fourth group) who could be followed up for 5 years, or until their deaths. The author favors the combined method of treatment for the first and second groups and irradiation alone for the rest.

Of the 11 patients with carcinoma of the body of the uterus 9 were hysterectomized and 2 were treated by irradiation. Seven of those hysterectomized and both of the patients treated by irradiation could be followed up for 5 years and all were found to be alive and well at the end of that time. There was 1 surgical death in this group and the author raises the question whether exclusive irradiation is suitable for these cases, however he does not feel that he should criticize this common practice on the basis of only 3 cases.

The author recommends further clinico-statistical study of these cases which on the basis of his figures are not so rare as commonly believed.

JOHN W. BRIDGES, M.D.

Pons, L. M.: Radiotherapy of Cancer of the Neck of the Uterus (Tratamiento radioterápico del cáncer de cuello uterino) *Boi Soc obst gine. B Aires* 1946 25 368.

Because of the location of cancer of the neck of the uterus, biopsy is easily accomplished and serial sections of the sample obtained should be examined. By this means the status of the cancer and its amenability to treatment can be determined. This is done by observing the mitosis, vacuolization, phagocytosis and condition of the nuclear and chromatic substances. The sensitivity of the tumor to radiotherapy may be judged by the degree of changes in the various cellular constituents. From animal experimentation it was shown that the best results from radiotherapy were obtained when the circulation to the parts was unaltered by any operation performed previously.

Examination of the cancer should reveal the grade of the tumor from which the prognosis may be determined. Histologically there are two types to be considered: one in which the cells are undifferentiated and the other in which the cells are discernible. The first is radiosensitive and the latter is more or less radioresistant.

There are four groups into which cancer of the neck of the uterus may be classified:

1. The type in which the lesion is limited to the neck alone. This form is amenable to Wertheim's operation and radiotherapy. It has been referred to as the precancerous lesion.

2. The type in which there are beginning cancerous changes with a tendency toward extension to the uterus, parametrium, or vagina.

3. The type in which the cancer is definite and there is infiltration into the rectum, parametrium, and all adjacent structures with fixation of the organs involved.

4. The type with all the features of type 3 and with vesicovaginal and rectovaginal extension and metastasis to distant organs.

Treatment is regulated according to the radiosensitivity or radioresistance of the tumor. The dosage should not exceed the resistance of the vaginal cells. The method of applying the radium cartridges and the quantity for each location are given. It is be-

lieved that the results of telecurietherapy are inferior to those obtained when focal curietherapy is combined with regional roentgen therapy.

The patients are divided into three groups: (1) those with fever, (2) those with neoplastic infiltration into the vagina, and (3) those with hemorrhage or with a cauliflower type of lesion.

In the beginning the first and second groups are given roentgen treatment, and the third group is given radium treatment, the radium being inserted with a tampon if necessary. The various reactions and accidents which might occur during the course of therapy are discussed.

STEPHEN A. ZIDMAN, M.D.

ADNEAL AND PERIUTERINE CONDITIONS

Valla, G. and De Gaudenzi, C.: Histologic Characteristics of Cutaneous Tumors in Dermoid Cysts of the Ovaries (Caratteristiche istologiche del tessuto cutaneo nelle cisti dermoidi dell'ovale) *Ginecologia Tor* 1945, 2 355.

The pathogenesis of ovarian embryomas is still obscure and there is no agreement among authors as to their proper classification. Two groups may be distinguished: (1) dermoid cysts with sebaceous contents, of benign character, and (2) teratomas in the strict sense of the word, which are usually solid, have a tendency toward malignant degeneration, and may be considered as true blastomata. The term "teratoma adultum" has been applied to dermoid cysts, and the term "embryonal teratoma" to immature formations. A subdivision into epidermoid cysts, true dermoid cysts (containing skin, hair and glands), complex dermoids (containing teeth and osseous structures) and complex teratomas (containing various tissues and organs) is not justified because all such formations possess plurigerminous properties.

According to one hypothesis, dermoid cysts of the ovaries derive from the residue of the wolffian bodies. Another theory maintains that metaplasia of the cells of Pflüger's tubules is responsible for the formation. Another school of thought holds that parthenogenesis is the responsible factor and according to some authors, the dermoid cysts derive from aberrant somatic blastomeres.

The authors' histologic studies showed that all structures found in dermoid cysts are homologous to tissues of the adult organism. The authors gave particular attention to the study of the epidermis, dermis, elastic tissues, sebaceous glands, sudoriferous glands, and the hair and its follicles. No deviations from similar normal structures of the adult organism could be found with the exception of very slight variations in the structure of the hair. The authors conclude from their investigations that Wilms' concept of the genesis of dermoid cysts is correct. The formation may be considered as an ovarian parasite or rudimental embryo capable of giving origin to any kind of organs or tissues.

JOSEPH K. NARAY, M.D.

Fortini E.: A Clinical Contribution to the Subject of Tubal Antiperistalsis (Contributo clinico sull'antiperistaltica tubarica) *Riv. obst. gin.*, 1946 1 105

A 36 year old married woman who had had 3 previous normal deliveries and nothing suggesting an adnexitis at any time, suddenly developed menstrual irregularities and was brought to the hospital with pains in the lower abdomen and constant although not serious metrorrhagia. Palpation, which was very painful, revealed a large soft uterus and a large sausage shaped mass in the pouch of Douglas to the left of the uterus. Puncture of the pouch released about 30 c.c. of dark colored blood together with a few small clots. Laparotomy uncovered a large firm whitish clot in the pouch and the sausage shaped mass which proved to be the tube with the pavilion and a portion of the ampulla invaginated over the proximal portion of the tube. The left tube was excised, which was followed by recovery.

Microscopic examination of the excised specimen exhibited evidence of a chronic inflammatory process everywhere in the tube but no sign of a polyp or other tumor or process to correspond to the usual concept of the origin of the invaginative process in the intestine. There was no evidence of nidation of the ovum indicating tubal pregnancy however the clotted mass lying free in the pouch of Douglas was found to contain syncytial and Langhans cells.

The author believes that this was actually a case of tubal abortion provoked by the painful palpatory examination and that the process of invagination was initiated by powerful antiperistaltic contractions of the smooth musculature of the tube.

JOHN W. BRIDGEMAN, M.D.

Murray E. G., and Cirio M. A.: Primary Tubal Epithelioma; Observations (Epitelioma tubario primitivo Dos observaciones) *Bol. Soc. obst. gin. B. Aires* 1946 25 435

Primary tubal epithelioma is a relatively rare lesion. This article presents in detail the twelfth and thirteenth case histories of the disease to be reported in the national literature of Argentina.

The first patient was a 57 year old female whose symptoms included a leucorrhoea and the existence of a fixed parametrial mass. At operation total hysterectomy was done and the microscopic diagnosis revealed an alveolopapillary epithelioma with extension to the ovaries, the broad ligament, and all layers of the uterus. STEPHEN A. ZIEGLER, M.D.

EXTERNAL GENITALIA

Meigs, J. V.: The Vaginal Smear *J. Am. M. Ass.* 1947 133 75

In 1923 Papanicolaou demonstrated his ability to make a diagnosis of cancer of the uterus by the observation of single malignant cells in the vaginal secretion. At the Massachusetts General Hospital, Boston 2 749 cases were studied with an error of only 3.2 per cent in diagnosis.

A positive smear indicates that careful further studies both by smear and by biopsy are indicated. A negative smear indicates that at the time it was taken cancer cells were not found on the slide. If the appearance of the cervix is suggestive, more smears must be taken because in certain instances shedding of the cells does not occur. Six and one-tenth per cent of 339 cancers did not show malignant cells. The smear diagnosis is important, but how far one is to go in the treatment of patients with a positive smear and a negative biopsy has not yet been decided.

Directions for staining methods or the method of diagnosis of individual cells have been included in numerous articles and in Papanicolaou and Traut's monograph. The nucleus of the cell is the main diagnostic criterion. The cancer cell has a large abnormal nucleus, and in groups a variation in size and shape is obvious. The large nuclei of cells from cervical cancer are radically different from those of the normal cells of the cervical epithelium. It is important to note the paucity of cytoplasm compared to the amount seen in the normal cell. In the cancer cell the large nucleus takes up most of the cytoplasmic space and the ratio of nucleus to cytoplasm is different from that in the normal cell. In cancer of the endometrium the same criteria are true but there is less variation in the size and shape of the nucleus. The presence of histiocytes and many leucocytes is a suspicious observation but is not diagnostic. The most important observation is the abnormal nucleus and its size in relation to that of the rest of the cell. Diagnosis by vaginal smear is painstaking and slow, and 30 minutes is not too long for the examination of a slide. Well trained technicians should be used to screen out negative slides, but in the process of screening suspicious cells should be noted, marked, and presented to the expert for final decisions.

It is easier to diagnose cancer of the cervix than cancer of the endometrium. It is obvious that the individual cancer cells are cancer cells, and even though the tumor cannot be found at biopsy never theless it must be there. The number of errors for false positive smears is now at 2.0 per cent. It is possible also for the cytologist to miss cancer when it is present in the patient. In 3.5 per cent of the cases of cervical cancer in which the slides were called negative, re-observation still did not show signs of tumor cells on the slides.

In the diagnosis of cancer of the endometrium there is an occasional confusion in calling cells malignant that are definitely not cancerous, and vice versa. The diagnosis of endometrial cancer calls for more expert observation than does that of cancer of the cervix. The error of false negative observations in endometrial cancer is 2.0 per cent.

In the series of 2 749 cases are included 339 cases of cancer. In 25 of these either carcinoma was unsuspected before a vaginal smear was taken or the vaginal smear was of great aid in the primary diagnosis.

The vaginal smear is of special value in following up cases of carcinoma treated in the past by radia-

tion, in which the patients are watched routinely in the tumor clinic for possible recurrence of their disease. It may be impossible to tell clinically whether disease is present, and it is difficult to obtain specimens for biopsy from irradiated patients so that some screening method by which certain cases can be chosen for further study is of great value.

This method is not an office procedure. It should be interpreted by those trained in cytology and in the smear method of making a diagnosis.

MISCELLANEOUS

Wharton, L. R.: Congenital Malformations Associated with Developmental Defects of the Female Reproductive Organs. *Am. J. Obs.*, 1947, 53, 37.

Although ovarian failure is often due to some endocrine disorder which secondarily affects ovarian function, there are certain cases in which this failure to function is due to agenesis and lack of follicular epithelium. The characteristic feature of this condition is a complete lack of ovarian epithelium. Serial sections of the ovary in the case of a woman with this condition failed to show any ovarian follicles. Individuals of this type show a complete lack of development of the breasts or reproductive organs, amenorrhea, and a lack of function of the ovaries. Other endocrine glands are normal. The author points out that many of these patients have other abnormalities of a generalized nature, such as retardation of growth, coarctation of the aorta, webbed neck, eye defects, congenital deafness, spina bifida, and mental retardation. This leads to the suspicion that the genetic fault is general and one of germ plasm defect. Since in these cases there is no other defect of the urogenital tract, it appears that the agenesis is present in the primordia of the germ cells and that it is there before the cells migrate to the gonadal folds. This would also suggest that germ cells do not originate in the urogenital folds. Since these cases developed female features normally and in the absence of any ovarian tissue, it seems as if sex differentiation takes place in the fetus without control of the gonad of the fetus.

Malformations of the müllerian ducts, bicornuate uterus, absence of the uterus, absence of the vagina, and vulvovaginal anus are often associated with abnormalities of the urogenital tract. Such cases are reported with findings of ectrophy of the bladder, ectopic kidney, horseshoe kidney, absence of a kidney, and ureteral malformations. The clinical value of routine intravenous urography in the presence of reproductive tract anomalies is stressed.

JOHN R. WOLFF, M.D.

Zondek, B.: Sterility in Woman. *Harvard Tel.* A 1, 1946, No. 2.

Only selected aspects of sterility are discussed. The observations are based on a personal material of 2,000 patients treated in the last 9 years.

There is a relation between cervical stenosis and

sterility. In spite of the relatively small size of sperm cells. A sound is usually passed into the uterus, though the author is not impressed with this maneuver as a therapeutic measure. The author found about 3 per cent of cases to be due to retroflexion of the uterus. He believes the explanation to be (1) the increased congestion of the endometrium, making it unsuitable for nidation, and (2) the kinking of tubes incident to this condition. He believes also that it should be treated by the Alexander Adams' suspension operation, which operation he performs in 10 to 15 minutes. His rate of success has been about 40 per cent. Other causes of sterility must of course have been ruled out. Eleven per cent of anovulatory cases were found. It is probable that the anovulatory cycle is common both during maturation and the climacterium. However it is wrong to ascribe sterility to a persistent anovulatory state on the basis of the result of a single examination.

The author believes that "uterine glycopenia" is a cause of sterility, this he found in 15.4 per cent of sterility cases. The diagnosis is based upon a chemical analysis.

The properties of the tubes play an important role in sterility. The two diagnostic methods are x-ray examination of the tubes by metroradiography and the method of insufflation of J. C. Rubin. Both methods are designed to show whether the tubes are patent but do not indicate whether the ovum can pass the tubes. Sterility can result if the tubal aperture is excessively distant from the ovary. Minute changes of tubal function can lead to sterility. Proper tubal function depends upon (a) tubal musculature, (b) nervous mechanism, and (c) hormonal stimulus.

As well as being diagnostic, the application of the methods discussed can in certain cases also be of definite therapeutic value.

Tuberculosis of the genital organs and its relation to sterility is important in Palestine. Zondek found, in a total of 950 curettages, 1 per cent of cases of tuberculosis of the uterine mucosa. None can say in what percentage of sterility cases tuberculosis of the adnexa is the responsible factor. If a diagnosis of tuberculosis of the uterine mucosa has been made, salpingography and perturbation are definitely contraindicated. Pregnancy is not impossible although tuberculosis of the uterine mucosa may be present.

With regard to tubal obstruction, hope for success exists only if the obstruction is caused by adhesions at the abdominal ostium of the tube. A cure of tubal obstruction which arises from an internal inflammation is very unlikely. Salpingostomy is therefore an operative intervention which hardly deserves to be called a therapeutic measure.

Myomectomy was performed in 113 cases of myoma. Twenty-six of the patients in this group later became pregnant and gave birth to healthy children. The percentage of success was therefore about 23 per cent. In cases in which delivery by cesarean section had been necessary, the author was impressed by the absence of any recurrence of the myoma and by the normal aspect of the uterus.

Endocrine disturbances as a cause of sterility are touched upon briefly. The fact that administration of small quantities of estrogenic hormone can lead to favorable results in cases of sterility is insufficiently appreciated. The results of administration of gonadotropic hormone in women have not so far been satisfactory.

In some cases disturbances of general metabolism lead to sterility. Hypothyroidism is especially important in this connection.

The author concludes with an appeal: Honor the sanctity of the fertilized ovum!

DANIEL G. MORTON, M.D.

MacLeod, D.: Endometriosis; A Surgical Problem. *Brit J Surg* 1946 34: 109

The term endometriosis implies the invasion by the endometrium of tissues to which it is foreign. Of the sites in which such invasion takes place, the uterus, ovaries and the peritoneum of the pouch of Douglas are by far the most conspicuous and the literature on this aspect of the subject is already very large. From time to time, however, cases are recorded in which the focus is situated in tissues either just outside of the genital tract, as the bowel, the navel, bladder and ureter or on the very fringe of it, such as the round ligament in the groin or the perineum.

In the author's Hunterian Lecture he deals mainly with extragenital endometriosis first, because not much has been written about it and second, because it is of interest to all surgeons whose province is the abdomen and third, because it throws a light on the much debated questions of genesis and method of spread of endometriosis in general.

In its simplest form endometriosis arises by direct invasion. Direct invasion however does not explain the appearance of endometrial tissue in situations remote from the uterus, and Sampson produced the implantation theory, which states that endometrial cells pass through the fallopian tubes during menstruation and become implanted on the ovary and other structures in the pelvis, particularly the peritoneum in the pouch of Douglas.

Ivanoff and others advanced the serosal theory which holds that under certain conditions the peritoneum has the power to undergo metaplasia and reproduce tissue resembling endometrium because it is developed from the same structure as the uterine mucosa, namely the splanchnopleure.

Finally there is the view that endometriosis arises by lymphatic spread from the uterus, in much the same way as a malignant neoplasm metastasizes by means of the lymphatic system. Strong support for this view has been afforded by the discovery of islands of endometrial tissue in the lymph glands and even in the lymphatic ducts themselves.

The phenomenon of endometriosis is unique in this respect that a whole normal adult tissue—not a single type of cell—transplants itself and grows in tissues foreign to it. Throughout active sexual life the endometrium is renewed every month with the

result that it never grows old. In fact, it is a Peter Pan among tissues perpetually retaining that vigorous growth propensity which makes it peculiarly suitable for tissue culture. Human endometrium was grown successfully in vitro.

In the case of endometriosis of the ovaries and pelvic peritoneum the most popular explanation is the spill theory of Sampson and this theory is also adequate as far as surface endometriosis is concerned.

However from a survey of all the facts, endometriomas wherever they occur are the result of lymphatic permeation of the endometrium. The occurrence of tubal spill cannot be absolutely disproved, but when we have a hypothesis adequately covering all the known facts it seems unnecessary to put forward a second one which accounts for only a few of them.

Endometriosis must be accorded a position somewhere between benign and malignant growths, two separate states of which the true relation has so far escaped the most searching scrutiny.

Is it too much to hope that further study and research regarding this problem will reveal the key to the essential nature of malignancy itself?

HARRY W. FINK, M.D.

Ahumada J. C. and Nogués, A. E.: Perforating Fornical Endometriosis. 12 Cases (La endometriosis fornical perforante: a propósito de 12 observaciones). *Obst gín inf-amer* 1946 4: 651

Of 5,600 gynecologic conditions treated in the authors' clinic, 3.6 per cent (12 cases) were endometriosis with rectovaginal extension and vaginal perforation.

The symptomatology included metrorrhagia, intermenstrual bleeding, rectal pain on menstruation and defecation, and symptoms of occlusion.

Examination showed nodular infiltration which varied in appearance according to the stages of development of the lesion. There were three types: the solitary lesion with apparently normal adjacent genital organs, the endometrial adnexal transplant, definitely an extension from the adjacent ovary, and the lesion with uterine involvement and infiltration and spreading from the vagina.

Treatment depends upon the state and age of the patient, and the degree of extension of the lesion. When surgery is no longer feasible, roentgenologic castration is indicated. Radium seems to produce little benefit, but complete extirpation offers a good prognosis. A detailed report of 12 of such cases is appended.

STEPHEN A. ZIEGLER, M.D.

Hertig, A. T. and Sheldon W. H.: Hydatidiform Mole—A Pathologicoclinical Correlation of 200 Cases. *Am J Obst* 1947 53: 1

The purpose of this report is to determine what, if any correlation exists between the histologic appearance of a hydatidiform mole and the subsequent clinical course of the patient with respect to the development of chorionic malignancy. The authors have examined a series of 200 hydatidiform moles.

gathered consecutively over a period of 11 years from 100 medical communities in the eastern half of the United States. Follow-up data on 94.5 per cent of all the patients are available.

The authors have classified hydatidiform moles into the following six groups according to their histological morphology:

1. Benign hydatidiform moles—no hyperplasia to slight hyperplasia of the trophoblast.
 2. Probably benign hydatidiform moles—slight to moderate hyperplasia of the trophoblast.
 3. Possibly benign hydatidiform moles—hyperplasia with slight anaplasia of the trophoblast.
 4. Possibly malignant hydatidiform moles—variable hyperplasia and moderate anaplasia of the trophoblast.
 5. Probably malignant hydatidiform moles—variable hyperplasia and marked anaplasia of the trophoblast.
 6. Malignant hydatidiform moles—exuberant hyperplasia and marked anaplasia with the trophoblast often invading the endometrium.
- a. Chorioepithelioma *à suu*—morphologic malignancy plus endometrial invasion
 - b. Syncytial endometritis—accentuation of syncytial placental site plus chronic infection
 - c. Choroidadenoma destruens—invasion of myometrium by malignant mole but without metastasis.
 - d. Choriocarcinoma—variable picture in uterus but invariably metastases cause death.

There is a marked but not an absolute correlation between the degree of apparent molar malignancy and the tendency of the patient to develop some grade of chorionic malignancy. In 73.5 per cent of the entire series there was no subsequent development

of either pathologic or clinical malignancy as judged from the follow-up data available in 90.5 per cent of the cases in this particular group. Various grades of chorionic malignancies (group 6) occurred in 26.5 per cent of the entire group. The prognosis of all grades of chorionic malignancy is good except for the relatively uncommon (3%) invariably fatal choriocarcinoma. In the first three grades of chorionic malignancy which are all curable if properly treated, clinical evidence of malignancy is usually shown by continued postmolar vaginal bleeding and/or subinvolution of the uterus. A policy of clinical watchful waiting may be followed until such objective evidence of malignancy develops without increasing the danger to the patient from chorionic metastases. Such individual clinical conservatism will save many uteri that might otherwise be needlessly sacrificed in haste merely because the patient has passed a hydatidiform mole.

Chorionic gonadotropic hormone tests are of little or equivocal value during the period when treatable clinical malignancies are first developing—an average of 35 days after expulsion of the mole. However, postmolar vaginal bleeding and subinvolution of the uterus are invariably present and indicate the need for at least a uterine curettage with the probability of a subsequent hysterectomy. Curettage was often done in this series, which shows that the operation *per se* does not increase the danger of subsequent metastases. By the adoption of a conservative attitude of scientific apprehensive expectancy many uteri that are now needlessly removed will be saved without appreciable increase if any of the death rate from chorionic malignancy.

JOHN R. WOURT, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Harris, R., Tchertkoff I. G., and Greenwald, L.:
Acute Leucemia and Pregnancy *Am. J. Obst.*,
1947 53 142

The authors report the combination of acute myelogenous leucemia in a 34 year old gravida 2 who was 5 months pregnant at the time of her admission to the hospital. At that time she entered because of a severe respiratory infection. The leucemia was diagnosed by a routine examination of the blood at that time. It was confirmed by bone marrow examination.

Penicillin therapy controlled the infection but did not influence the blood picture. A spontaneous abortion occurred shortly following her admission to the hospital. An autopsy on the stillborn fetus showed a normal blood picture. The patient had 2 recurrences of sepsis and died 20 weeks after the original admission to the hospital. There was no autopsy.

JOHN R. WOLFF M.D.

Philpott N. W., Latour J. P. A., and Van Dorsser G. J. L.: Review of Cases of Rh Isoimmunization during the Past 5 Years in the Royal Victoria Montreal Maternal Hospital *Am. J. Obst.* 1946 52 926

The authors review the cases of 1214 obstetric patients delivered during the 5 year period ending December 31, 1945 for the purpose of studying Rh isoimmunization as a cause of hemolytic disease of the newborn. The review yielded 37 cases, diagnosed clinically, of which 30 were subsequently considered as proved an incidence of 2 in 404. Among these 30 cases there were 19 live births. Thirteen of the infants are still living 8 are normal 3 are definitely subnormal and the condition of 2 is unknown.

Hemolytic disease of the newborn occurred most frequently in the second and third pregnancy. Rh antibodies were demonstrable in the majority of mothers postpartum. Fetal mishaps were of high incidence in the total number of pregnancies in these mothers but no other complications of pregnancy could be related to Rh isoimmunization. Interruption of pregnancy at the thirty-sixth week has not yielded good results.

Analgesia and anesthesia at the time of delivery must be well chosen. Any type which diminishes the oxygen-carrying content of maternal blood should be avoided. Early diagnosis is essential in the adequate treatment of the affected baby. The babies of all Rh-negative mothers whether they exhibited antepartum antibodies or not are typed for the Rh factor immediately after delivery. Daily hemoglobin estimations are done on all Rh-positive babies for the remainder of their stay in the hospital. If the hemoglobin level of the heel blood is below 90 per cent at birth or if the daily drop is more rapid than normal estimations are done two or three times

daily and repeated small transfusions (10 c.c. per pound) of Rh-negative whole blood are given. Mother's milk is interdicted because of the high titer of Rh antibodies in some patients.

JOHN R. WOLFF M.D.

Raynaud, R. and D Eshougues, J. R.: The Pathogenesis of the Herpes of Gestation (A propos de la pathogenie de l'herpes gestationis) *Ann. endocr.*,
Par., 1946 7 238

A septipara 39 years of age developed generalized herpes at the fifth month of pregnancy which persisted until term and cleared up promptly after delivery. The lesions were grossly symmetrical and involved the whole body except for the palms, soles, and external genitalia. They appeared in crops and caused intensive and painful pruritus. The blood count revealed a leucocytosis of 15,000 with 27 per cent eosinophils. The herpes vesicles contained eosinophils in great number to the exclusion of all other cellular elements.

For 6 months after delivery the patient was free of symptoms. Then, simultaneously with the first menstruation a violent new attack occurred. The lesions were erythematobullous, the temperature rose to 40° C. and profuse uterine hemorrhage set in.

This new eruption occurring in the absence of pregnancy was checked promptly by the injection of male hormone (10 mgm. daily). After the second day the fever and rash diminished considerably, and after the fourth injection all symptoms had disappeared.

The authors consider the herpes of gestation as a special case of dermatitis herpetiformis (Duhring) and believe that it is caused by sensitization of the skin to estrogenic hormone. The sudden explosive outbreak, the eosinophilia of the blood and tissues, the ever increasing violence of the symptoms with each following pregnancy give evidence of the allergic character of the condition.

It is known that other allergic conditions like certain types of eczema, asthma, Quincke edema, and migraine are often in close relationship with the menstrual cycle and can be treated successfully with hormones which counteract the effect of folliculin (progesterone or testosterone). It has been demonstrated that folliculin continues to be secreted during pregnancy but it loses its effect because of the prevailing action of progesterone. After the third month of gestation, the luteinic hormone is replaced by the ever increasing folliculin produced by the ovary and the placenta. After delivery and expulsion of the placenta, this process is again reversed, and the hyperfolliculinemia is succeeded by a second luteinic phase in connection with the corpus luteum of lactation which inhibits the normal menstrual cycle. The foregoing explains why herpes gestationis never occurs in the first trimester of pregnancy i.e., during

the time that the organism is under the influence of progesterone. The onset of the attack coincides with the cessation of corpus luteum activity and the reappearance of folliculin. Therefore, it seems logical to assume that the disease is an example of hypersensitivity to folliculin, which is produced in excess during pregnancy. This theory is supported by the striking success of treatment with male hormone.

WERNER M. SOLMITZ, M.D.

Ramos, A. P.: Abdominal Drainage in Cesarean Section for Contaminated Cases. (El drenaje abdominal en la operación cesárea del caso impuro). *Obst. gín. lat-amer.* 946 4 7 5

The author believes that low extraperitoneal cesarean section is one solution to the problem of delivery in contaminated cases. He reports a mortality rate of 3.49 per cent and a morbidity of 23.7 per cent for 439 cases. In 188 cases in which sulfonamide therapy was employed the mortality dropped a little (2.13 per cent) whereas the morbidity remained about the same.

Penicillin is looked upon as a still more marvelous agent, and the synergistic action of the two drugs gives greater promise, but it is believed they should be used complementarily to surgery.

In regard to the use of drains in extraperitoneal cesarean section the author believes, as Sterling Mueller, that the tendency of not employing effective drainage of the peritoneal cavity because sulfonamide has been applied is to be lamented and that the old rule "When in doubt drain it" is as valid as it was before the use of sulfonamide therapy.

The classifications of Winter and Bureau both present three groups of contaminated cases which might come to surgery: (1) those in which contamination is suspected because they have been handled vaginally without consideration for asepsis; (2) the infected cases with a temperature of 38° C. and (3) those which have been repeatedly examined externally or without care of asepsis with high fever and contaminated amniotic fluid.

It is in these last two types that drainage complemented with antibiotic therapy is particularly recommended as definitive treatment.

STEPHEN A. ZIEGLER, M.D.

LABOR AND ITS COMPLICATIONS

Baena, A.: Cesarean Section. *Philippine J. Surg.* 1946, 7 5

Before the time of Pasteur and Lister a cesarean operation almost always brought death. The author states that now with asepsis and antiseptics, improved technique, and the exercise of good obstetric judgment, the operation is attended by a very low maternal mortality. The safety of the operation has been so definitely demonstrated that many abuses have been committed in its name. In many cities of the United States the incidence of cesarean section varies from 2 to 3 per cent. To cut down this incidence many hospitals are now passing rules making

it mandatory to hold a consultation before a cesarean section is performed.

Material is presented concerning 228 consecutive cesarean operations which the author performed in the Philippines. The incidence of cesarean section in the Philippine General Hospital from 1927 to 1940 was 0.77 per cent (364 cases among 48,481 births). Ten years earlier it was 0.31 per cent. The incidence among the author's private patients was 1.35 per cent. This higher incidence was due to quite a number of elderly primiparas. Among those between 35 and 40 years of age there were 35 cases, and among those between 40 and 45 years of age there were 5 cases. There is greater rigidity of the cervix and less luxation of the pelvic joints in elderly primiparas.

The classical section was employed in 30 of the 228 cases. When conditions demanded quick operation and if the case was judged to be clean, classical section was used. The classical approach is replaced more and more by low section which has more proved advantages: namely, it offers a smoother postoperative course, better chances of combating infection should it develop, a lower mortality rate and a scar which resists rupture in subsequent pregnancies and labors 16 times more readily than the scar following classical section.

The radical section was employed in 5 of the cases and was chosen because of frank infection and of ablatio placenta with very advanced intramural hemorrhage in which the uterus loses its power of contraction and therefore requires amputation after it has been emptied of its content.

Vaginal cesarean section was employed only once in this series in a case with a dead fetus in utero. The author has performed vaginal hysterotomy many times for removal of the fetus more than 3 months old and for hydatidiform mole demanding fast evacuation through an unyielding cervix. Waters' technique of extraperitoneal cesarean section was attempted in 1 case of placenta previa that was potentially infected. It did not succeed because of a poorly formed lower segment. The operation was continued as a transperitoneal low cervical section and the patient survived.

The indications for cesarean section in puerperia are presented. Placenta previa comprises 40.3 per cent of the indications for section. With only 2 or 3 cm. of the cervix open and rigid, and with no signs of actual infection, cesarean section is the best means of preventing future blood loss. Further separation of the placenta with more stretching of the lower segment of the uterus is inevitable unless treatment intervenes. Two schools of thought exist for the treatment of ablatio placenta. The conservative form of treatment, even in case of concealed hemorrhage, has a mortality of 2.9 per cent. The radical school advocates cesarean section as the better mode of delivery. The mortality rate in this group was 14.3 per cent.

The author discusses the circumstances of rigidity of the cervix, cephalopelvic disproportion, tumor previa, and the repeat section. In this series there

were 2 maternal deaths reported, 1 death occurring in a case of antepartum eclampsia. The fetal loss totaled 31. There were 9 stillbirths and 22 neonatal deaths. If a correction is allowed for the death due to eclampsia, the corrected mortality rate would be 0.49 per cent for the low section. Several of the cases of low section were poor risks against infection. The results, despite the big risks, confirm the claim that low section takes good care of infection. Under low section the postoperative course is seldom stormy.

HERBERT F. THURSTON, M.D.

Benoliel, W.: The Relief of Labor Pain with Continuous Caudal Anesthesia (Il parto indolore con l'anestesia caudale continua). *Riv ostet gin.* 1946 1: 53.

The author's study of 30 cases of labor with the use of continuous caudal anesthesia by means of the American method of administration revealed that 73 per cent of the patients had complete anesthesia while the remainder had partial anesthesia. No ill effects were observed in the newborn, and complications in the mother were rare. No major changes in pulse, blood pressure, and respiration were noted. The maximum drop in blood pressure was 12 mm. Hg (in only 3 cases) while the maximum increase in pulse was 26 and the maximum increase in the respiratory rate was 10.

In 10 per cent of the cases the author observed pallor, dryness of the mouth, excessive pulsation of the temple vessels, and nausea and vomiting. There were no mortalities.

The author concludes that although this form of anesthesia is not perfect, it is worthy of use.

ARTHUR F. CIPOLLA, M.D.

PURPERIUM AND ITS COMPLICATIONS

Wolfa, S. A., and Podowitz, P.: Late Postpartum Hemorrhage. *Am J Obst* 1947 53: 84.

Late postpartum hemorrhage indicates prolonged or excessive uterine bleeding beginning after the first day of delivery. Retention of the placental fragments is the most frequent cause of this condition. Retained fragments may be expelled spontaneously. More commonly however recurrent episodes of bleeding require surgical intervention. The formation of placental polyps is infrequent. Bleeding may be produced by noninvolution of the placental site as evidenced by poorly thrombosed veins which later reopen and cause bleeding. Retention of abnormal amounts of decidua vera during separation of the placenta and membranes may cause the milder form of late postpartum bleeding.

Because of the frequency of retained placental tissue as the cause of this bleeding the authors believe that the first step in management of this problem is digital exploration of the uterine cavity. Only by this method can a retained placental fragment be discovered and removed. If none is present, noninvolution of the placental site or separation of excessive amounts of decidua slough is the causative

factor of the bleeding. If separation of the retained placental fragment cannot be accomplished with the finger, the use of the curette or ovum forceps is safe. Such operative intervention for active bleeding in febrile cases is followed by moderate morbidity.

JOHN R. WOLFF, M.D.

NEWBORN

Tortora, M.: Biological Aspects of the Vaginal Secretion during the Genital Crises of the Newborn (Aspetti biologici del secreto vaginale durante la crisi genitale delle neonate). *Arch ostet gin* 1946 51: 290.

A study of the vaginal secretion of 30 babies within the first 2 weeks of extruterine life revealed a high vaginal acidity, a flora in which the *Doederlein bacillus* was present, an increase of leucocytes and an increase of the cells in the stratum spinosum.

In the first 12 to 14 hours after birth, the vagina of the newborn is free from bacteria. However about the second or third day the vaginal flora contains mainly streptococci and staphylococci. From the third to the seventh day the *Doederlein bacillus* is prevalent, after which the streptococci and staphylococci again are present in quantities.

With Papanicolaou's technique of staining there was found a desquamation of the vaginal and uterine epithelium on account of the cessation of the maternal follicular hormone in the crises. As a rule, hemorrhage accompanies this stage as it is caused by the degeneration and elimination of the cervical mucosa which participates more intensely than the endometrium in this regressive phenomenon.

ARTHUR F. CIPOLLA, M.D.

Laffont, A., and Bonafos, M.: The Influence of Sulfonamide Therapy in the Mother on the Infant (Influence sur l'enfant de la sulfamidotherapie maternelle). *Gyn obst Par.* 1946 45: 447.

The widespread use of sulfonamide therapy both prophylactically and therapeutically in obstetrical practice is well known. The authors have studied the effects on the newborn of such therapy instituted in the mother antepartum and postpartum during the nursing period.

In their studies on sulfonamide therapy in the pregnant woman, the authors concurred with many others that there was a transplacental passage of sulfonamides, which has been proved by animal experimentation. They determined that the blood level of sulfonamide was the same in the mother and fetus from 3 to 5 hours after injection; furthermore, this level was proved to be sufficient to protect the infant from any disease of the mother either blood borne or contracted at the time of parturition (puerperal sepsis or gonorrhea). Although authorities generally agree that sulfonamide therapy in the mother has no ill effect on the fetus, yet the possibility of idiosyncrasy to the drug and the possible effects when the drug is given over a long time demand caution against indiscriminate usage.

The authors cite 130 cases in which sulfonamides were administered to pregnant women. 50 per cent of these cases were followed by miscarriages, premature fetal death, premature labor, icterus of the newborn, or congenital anomalies. The authors, however, do not implicate the sulfonamides as the causative factor in fetal death and debility but, rather, the mother's disease for which the sulfa drugs were given (pneumonia, gonorrhea, pyelonephritis, osteomyelitis). The incidence of icterus of the newborn in statistics compiled before the days of sulfonamide therapy is no less than that reported by the authors in their series.

There were 18 neonatal deaths in the authors' series of these, 11 demonstrated what the authors call sulfonamide syncope of the newborn, a condition which they charge to sulfonamide toxicity. The clinical picture in the newborn is that of livid pallor, prolonged apnea, and generalized hypotonia from which the authors conclude that the sulfonamides exert a toxic effect in a few cases on the nervous system, heart, lungs, liver and hematopoietic tissue of the fetus. However, this effect fortunately does not compromise the future of the infant, except rarely. These exceptions can be explained by a predisposition of the infant to prolonged antenatal administration of the sulfonamides begun late in pregnancy. It is important to note that sulfonamide therapy, even when massive and prolonged, is not accompanied by any fetal damage if it is instituted early rather than late in pregnancy. But, in spite of this occasional idiosyncrasy of the fetus to sulfonamides, the authors agree that in the clearing of certain maternal infections by sulfonamides, the prognosis for a normal healthy infant is much better and the percentages of premature labor so high in acute infections, are much reduced. Also the chance of spread of maternal infection by the blood stream to the fetus is avoided, and the chance of an almost certain intrauterine death of the fetus in an amniotic fluid is obviated.

With regard to the effect of maternal sulfonamide therapy on the nursing infant, the authors first demonstrated the presence of sulfonamides in the milk, then evaluated the quantity absorbed by the infant and the level of the drug therapeutically effective in the newborn. They found that the drug appeared in the milk from 3 to 6 hours after absorption of the first dose and persisted during the course of treatment up to several hours after its discontinuance. The level in the milk is generally 65 per cent, the same as in the maternal blood stream. The amount of drug absorbed by the infant is far below the therapeutically effective level (about one-tenth) for an infant, but the authors believe that from the point of view of prophylaxis, particularly if the mother has an infectious disease, this level is sufficient and in some cases is of definite advantage to the infant. Thus, the benefits to the fetus of sulfonamides administered to the mother antepartum in preventing infectious processes may be continued by allowing the infant to nurse from the mother who

is still receiving the drug. A normal nursing infant of 9 months theoretically would absorb from 10 to 15 mgm. of sulfa drugs in a day.

The authors find, however, that sulfonamides exert a definite inhibiting influence on the secretion of milk. This inhibition is observed particularly in primiparas. Of 15 cases reported by the authors, 12 showed definite hyposecretion of milk. Twenty nine out of 34 multiparas who had previously nursed infants and received sulfonamides both antepartum and postpartum were unable to satisfy the nutritive needs of their offspring. It was also found that if a nursing mother was given sulfonamides for some reason anywhere from 1 to 9 months after delivery her supply of milk definitely diminished even the public is aware that sulfonamides help to dry up secretions of milk.

The infant who receives sulfonamides in the mother's milk may occasionally show digestive, circulatory, respiratory or nervous difficulties. In some cases the infant refuses to take sulfonamide milk but will greedily take artificial feeding. Vomiting, diarrhea, and colic have been observed to coincide with sulfonamide therapy in the mother. Pale-ness and cyanosis together with irregularity of pulse and subnormal temperature have also been observed rarely there is an alarming apnea, abnormal respiratory pauses, and panting respiration. Nervous complications include hypotonia, and occasionally convulsions. Anemia is sometimes seen. All of these reactions were noted much more frequently in nursing infants whose mothers began taking sulfonamides after confinement.

Although the dose of active principle taken in by the nursing child is atomic, many factors enter into an exact interpretation of the chemotherapeutic index; this also is true in the question of idiosyncrasy in which low levels may be just as significant as therapeutic levels.

PHILIP B. CHASE, M.D.

MISCELLANEOUS

Zambonini, A.: Anomalies of the Umbilical Cord (Le anomalie del cordone ombelicale). *Riv. Ital. St.* 945, 3, 60.

Anomalies of the umbilical cord are common and are not only of anatomical and teratological interest, but when they interfere with function, they become of considerable clinical interest.

Anomalies of purely anatomical interest are the absence of one umbilical artery, the presence of supernumerary arteries or veins, bifurcation of the umbilical vein, cases of divided placenta in single births, and multiple cords, each of which carry an artery and vein.

The more important anomalies of the umbilical cord are those which are capable of causing a sphryxia or other injury to the fetus. The author discusses these at length and then gives a statistical report of the corresponding anomalies which occurred in 3,043 of 10,440 umbilical cords, (18.75%) in 10,295 deliveries at the Obstetrical and Gynecological Clinic at

Bologna from 1939 to 1943. Of these 10 295 deliveries, 145 were deliveries of twins.

In 1862 of the 2 034 cases presenting abnormality of the umbilical cord there was spontaneous delivery with no injury to the fetus in 140 cases the fetus suffered on account of the abnormality of the cord and in 41 cases death resulted.

Hematoma of the umbilical cord results from laceration of the vessels of the cord and the consequent flow of blood collects beneath the amniotic sheath. Hemorrhage is more often venous than arterial, but it can occur in any of the 3 umbilical vessels. Severe hemorrhage is comparatively uncommon.

Torsion of the umbilical cord results from movements of the fetus. The torsion is usually of mild degree and causes no harm to the fetus but it may be severe enough to shut off the umbilical circulation completely and cause asphyxia of the fetus.

False knots of the cord may result from such conditions as varicosities of the umbilical vessels or from accumulations of Wharton's jelly. These conditions rarely interfere with the maternal-fetal circulation.

Brevity of the umbilical cord may be a harmful anomaly when great enough tension is exerted on the short cord to interfere with the umbilical circulation. In the series of deliveries presented in this article, there were 45 cases of brevity of the cord, 36 of which terminated in spontaneous delivery and 9 resulted in pathological conditions with death of the fetus in 2.

Excessive length of the cord is a more common anomaly than brevity of the cord. Of itself it is not

dangerous, but when the cord becomes prolapsed or wound tightly around parts of the fetal body it may produce serious harm.

Coils of the umbilical cord around different parts of the fetus e.g. the neck, thorax, abdomen, or limbs, is a very serious complication of pregnancy. Multiple coils about the same part of the body often occur. In 1 185 cases of coils of the umbilical cord about the fetus which occurred in this series, delivery was spontaneous in 1 058 and caused pathological conditions in 127 with death of the fetus in 11.

Procentia of the cord is rare only 7 cases occurring in this series. In 6 of these delivery was spontaneous. In 1 case the fetus was dead, complete asphyxia having resulted from the procentia.

Prolapse of the umbilical cord is a very serious abnormality. Of 43 cases occurring in the series presented, 18 ended in spontaneous delivery and in 25 cases the delivery was pathological, with death in 19 fetuses.

True knots occur in cases in which the umbilical cord is of excessive length when there is excessive amniotic fluid when there are especially active movements of the fetus, and at times when the mother executes sudden and forceful movements. Of 57 cases of true knots of the umbilical cord presented in this series, 47 terminated in spontaneous delivery, while in 10 cases delivery was pathological. In 6 cases the fetus was dead.

This research into the anomalies of the umbilical cord demonstrates what an important part serious anomalies play in the life of the fetus.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Johnson H. T., and Nesbit, R. M.: 17 Ketosteroids in the Diagnosis of Adrenal Tumors. *Surgery* 1947 31: 184

Clinical syndromes involving masculinizing symptoms have long been recognized. Thomas Cook, in 1765 being the first to describe a child with changes probably due to excess androgens. Before 1933 there was great confusion over the etiologic factors involved in these syndromes. Suggested causative agents included adrenal tumors, ovarian tumors, thymic tumors and other vague endocrine disorders.

Ballock and Sequeira, in 1905 published a series of 11 cases of masculinization in women caused by adrenocortical lesions, and in 1913 Gallus introduced the term "adrenogenital syndrome."

In 1932 Cushing recorded a number of cases of masculinization in which basophil adenomas of the anterior lobe of the pituitary gland had been demonstrated.

Frequently no definite lesion of the endocrine glands is demonstrable, but the adrenal glands are usually enlarged and may contain small adenomas, which Cushing regarded as secondary. That a very similar syndrome may be caused by tumor or hyperplasia of the adrenal cortex also has been definitely established, and in these cases there is an excessive amount of 17 ketosteroids demonstrable in the urine. At present it is thought that both pituitary and adrenal mechanisms may be involved but there is no general agreement as to which is primary.

The differential diagnosis of the etiologic factors in these syndromes on clinical grounds alone is difficult. Roentgenograms of the skull, pentacel air insufflation, or pyelograms may be very helpful, and a tumor of the adrenal or ovary at times may be palpable. The recent evidence brought forth by Crooke and Callow that the adrenocortical tumor group may be differentiated by estimation of the greatly increased urinary androgens in these cases, thus becomes of great significance.

Estimation of the total 17 ketosteroids may therefore be of great value in differentiating adrenocortical lesions from pituitary, ovarian, and other disorders, but it does not distinguish adrenocortical hyperplasia from adrenocortical carcinoma, both of which have excessive androgen production. However it has been shown that the total 17 ketosteroid output can be separated into alpha and beta fractions, and there is evidence that whereas the alpha ketosteroids are produced by both the adrenals and testes the beta ketosteroids arise only from the adrenal cortex.

A survey of the literature reveals less than 35 cases of adrenocortical tumor in which the total 17 ketosteroid output has been determined and fractionation into alpha and beta portions has been performed in

only a very few. Three proved cases of adrenocortical carcinoma associated with markedly elevated total 17 ketosteroid excretion, in which fractionation into alpha and beta portions has been of definite value in the differential diagnosis are reported.

JOHN E. KIRKPATRICK, M.D.

Dodson, A. I.: Polycystic Disease of the Kidney. *J Urol* Balt. 94: 57 309.

In polycystic disease of the kidney the destruction of renal tissue results from pressure exerted by the gradual increase in size of the congenital cysts interspersed throughout the kidney. Most patients are beyond 30 years of age before the disease is recognized. Consequently it seems logical to operate on these patients as soon as the disease is recognized, excise a portion of the wall of the superficial cysts, and aspirate as many as possible of those which are deeply situated. From a review of the literature, it seems that most authors consider the treatment largely medical and prefer to resort to surgery only when there is obstruction, stone infection, severe hemorrhage or incapacitating pain. The principal objections to conservative operations in the treatment of polycystic kidneys are that fistula may result, infection may spread to the rest of the kidney and the results are very uncertain.

The author has followed the conservative plan in the past but reports 3 cases recently treated which cause him to question his former conservatism.

The first patient, a 36 year old female, had a history of attacks of kidney colic, often with fever for a 20 year period. Phenolsulfonphthalein elimination was 35 per cent in 1 hour. Both kidneys were infected with the *Escherichia coli*. Pyelograms showed only the characteristic changes of polycystic disease. Operation was done on each kidney; the cysts were opened and drained of purulent material, and in the course of about 6 weeks the patient was discharged with much improvement in her condition. Two months after operation the phenolsulfonphthalein excretion was 55 per cent, the pyelograms showed improvement, and the patient's general condition was better. She was seen at the end of 11 months when she was entirely symptom free.

The second patient, a 64 year old female, had had pain in the right lumbar area for 12 months. Pyelography demonstrated bilateral polycystic disease. Operation was performed on the right kidney with satisfactory recovery. With the exception of one episode of mild pyelitis on the right side, the patient has been asymptomatic for the 3 years that she has been followed up since surgery was done.

The author concludes that inasmuch as medical treatment has little to offer these patients and the course is always downhill more consideration should be given to surgical relief for the patient with this disease.

JOHN E. M. CRILL, M.D.

Kojen L. and Petkovic, S : Urinary Lithiasis following Osseous Wounds of War (La lithiase urinaire consécutive aux blessures osseuses de guerre) *Rev chir.*, Par 1947 66 14.

In an army urologic center the authors encountered 17 patients with war wounds of the skeletal or osseous system and urinary lithiasis. In 9 cases there was no associated wound of the urinary tract and the urine was sterile. Eight patients had in addition to their bone injury an injury of the ureter or bladder and infected urine.

While this is a relatively low incidence of urinary lithiasis when one considers the large number of bone injuries sustained in the war the authors have reached certain conclusions as to the relation between these injuries and the development of lithiasis.

In the etiology of post traumatic urinary lithiasis the following factors are significant.

1. The bony decalcification which is followed by hypercalcemia and hypercalciuria.
2. The immobilization necessary which favors decalcification of the entire osseous system.
3. Alterations in the kidney resulting from a greater elimination of lime salts.
4. Alterations in the kidney produced by microbes and toxins from the site of fracture.
5. Stasis resulting from prolonged rest and immobilization in a horizontal position.
6. Suppuration at the fracture site which creates favorable conditions for formation of urinary calculi.
7. The appearance of lithiasis more frequently after compound fractures of the femur.

The treatment of urinary lithiasis associated with fractures or bone wounds involves proper surgical care of the fracture site, adequate fluid therapy and early motion. Once lithiasis has occurred the treatment should be conservative. The stones are often small and will pass through the urinary tract spontaneously. If the stones will not pass spontaneously the authors recommend that the fracture site be immobilized adequately to permit the patient's transfer to a mineral spa and later return for operation. Patients should not be operated upon while their condition is favorable for the formation of urinary calculi.

BLADDER, URETHRA, AND PENIS

Prather G. C. and Petroff B. Bladder Neck and Spinal Cord Injuries. *J Urol* Balt. 1947 57 374.

A series of 129 cases of spinal cord injury, representing material accumulated in army general hospitals designated as centers for the care of such injuries was studied for evidence of changes in the bladder neck and posterior urethra. The anatomic changes were recorded by means of retrograde injections from the external meatus, of small amounts (from 25 to 30 c.c.) of radiopaque media with subsequent roentgenograms.

The authors' findings indicate that it is important to differentiate between partial and complete tran-

section of the spinal cord. The cases designated as those with partial transection show some evidence of voluntary motor power and sensory appreciation below the level of the lesion. Cases with complete transection show complete functional interruption of the spinal cord at a given level.

Dilatation of the bladder neck was the most important finding in this series. Here, in complete transection of the spinal cord *en cauda equina* the time element was an important factor. A greater number of dilated bladder necks were found 3 to 12 months after injury than 2 to 3 months after the accident. However, the period of time elapsing from the time of injury to the time when these studies were undertaken did not appear to be so important in cases of partial transection.

In complete transection of the cord *en cauda equina*, the bladder neck revealed some degree of dilatation in 30 of 36 cases, a ratio of 5 dilated to 1 normal. In partial transection 65 of 93 showed some dilatation, a ratio of 2 dilated to 1 normal.

A study correlating the level of injury with the presence of bladder neck changes indicated that dilatation of the bladder neck is predominant but not constant in cases with complete transection of the spinal cord and that dilatation is always present in complete transection of the *cauda equina*. In those with partial transection dilatation of the bladder neck is common and occurs with increasing frequency from the level of the cervical region to the *cauda equina*. The prevalence of dilatation was not affected by the bladder capacity, i.e. whether it was hypertonic or hypotonic.

The authors conclude that dilatation of the bladder neck is a common finding in patients with injury of the spinal cord.

De Souza Carvalho Netto J. N. A Study of Freyer's Operation Adenomatous Hyperplasia Drainage According to the Author's Method (Estudo atual da operação de Freyer. Hiperplasia adenomatosa com drenagem suficiente, pelo autor) *Rev. Brasil. Cir.*, 1946 15 411.

A great variety of conditions have been made responsible for so-called hypertrophy of the prostatic gland, e.g. syphilis, rheumatism, arthritis, gout, alcoholism, sexual abuses, a sedentary mode of life, habitual constipation, urethral strictures, cystitis, and calculi of the urinary bladder. However, all such conditions may be considered only as contributory factors. Hereditary factors and allergic conditions have also been mentioned in the literature. Neoplastic and infectious theories also find their defenders, while some writers consider hypertrophy of the prostate gland as a compensatory process for which changes in the testes are responsible.

The author focused his attention on rudimentary prostate glands which may be divided into two groups: subcervical and those of the trigonum.

Prostatic hypertrophy is not a diffuse hyperplasia of the entire structure but of separate foci, mainly a

Fig. (DeSouza Carnalho Net)

hypertrophy of the centrally located glands. Four types of hyperplasia may be distinguished glandular which is the most frequent on cystic fibro-glandular, and fibrous.

According to the members of the Cleveland Clinic, testes produce masculine and feminine sex hormones. An excessive secretion of the masculine hormone under the influence of stimulation by the hypophysis leads to an adenomatous hypertrophy of the prostatic urethra. The Amsterdam school is diametrically opposed to this theory maintaining that an excess of estrogens or other gonadotropic substances is the responsible factor and that therefore androgens should be administered to re-establish the normal equilibrium.

The author concludes from his studies that the term "hypertrophy of prostatic gland" should be replaced by "adenomatous hyperplasia of the prostatic urethra." Consequently prostatectomy should be replaced by adenectomy. The author describes the technique of suprapubic prostatectomy which he terms transvesical paraprostatic adenectomy. He considers proper drainage as the most important factor in the operative technique. To prevent contamination by the urine of the cavity created by removal of the glands, he employs a catheter with its proximal end so invaginated that 2 tubes are created the inner one drains the fluid from the bladder while the outer which carries several rows of holes, drains the secretions from the cavity underneath the bladder. The sphincter of the bladder fits around the tube just below its invaginated portion so that the bladder and the cavity below it do not communicate one with the other. The proximal end of this drain is attached with a string to the distal end of another

drain introduced through the cystostomy. A traction on the last mentioned drain disposes of the cuff on the lower drain, to facilitate its removal.

JOSEPH E. NARBY M.D.

Woodard H. O. and Dean, A. L.: Phosphatase Findings in Carcinoma of Prostate. *J. Urol.* Balt. 94: 57, 18.

Phosphatase is an enzyme which splits the phosphate radical from organic phosphorus compounds. Phosphatases occur in many tissues and differ in properties with their tissue of origin. They fall into two broad groups—those with a maximum activity in alkaline solution and those with a maximum activity in acid solution—and are known respectively as alkaline and acid phosphatases. In addition to differing in pH optimum phosphatases differ in their relative activities on various substrates.

Alkaline phosphatase. Bone and ossifying cartilage contain an enzyme which splits calcium glycerophosphate and calcium hexose monophosphate in alkaline solution. Alkaline phosphatases are abundant in bone, kidney and testicular mucosa. Normal values for serum alkaline phosphatase are given as 5 to 10 Bodansky units per 100 c.c. The major portion of the alkaline phosphatase in the blood serum originates in the bones and is rapidly excreted by the liver. When the bile ducts are obstructed alkaline phosphatase is not excreted and accumulates in the blood serum. Serum alkaline phosphatase cannot be used as a test of bone activity in patients with marked liver disease. Alkaline phosphatase is produced by bone as an essential agent in growth and repair. It is produced in large amounts wherever new bone is being formed or an attempt at new bone

formation is being made. The level of alkaline phosphatase in the serum usually reflects bone activity rather closely when liver function is normal. When cancer of soft part origin metastasizes to bone, and the lesions are osteoplastic alkaline phosphatase production is increased. Bone metastases from carcinoma of the breast, thyroid and kidney are usually osteolytic, while prostate carcinoma metastases are nearly always osteoplastic. In the former the serum alkaline phosphatase is commonly within the normal range in carcinoma of the prostate metastatic to bone it begins to rise early in the disease and may increase as much as 50-fold. It is emphasized that new bone formation is the result of excess alkaline phosphatase production rather than the cause of it.

Acid phosphatase. Prostate extracts and prostatic secretion contain an acid phosphatase which splits phenylphosphate alpha and beta glycerophosphate and hexose diphosphate. In man the activity of the prostate is 100 or more times as great as that of any other tissue. Cancer of the prostate retains the ability to produce large amounts of acid phosphatase which is characteristic of the normal adult prostate and distant metastases share this ability with the primary tumor whether the metastases are in bone or in soft parts. In metastatic areas in bone the acid phosphatase is produced by the tumor in the bone the alkaline phosphatase is produced by the bone around the tumor.

In Woodard's method sodium beta glycerophosphate is used as a substrate at a pH of 4.2 to 5.0 and normal values do not exceed 10 units per 100 c.c. and are independent of alkaline phosphatase readings. Because serum acid phosphatase is elevated in some patients with metastasizing carcinoma of the prostate the test is a valuable aid in diagnosing prostatic cancer and in evaluating the effect of treatment. The liver does not play a part in controlling the acid phosphatase of serum.

Of the patients with carcinoma of the prostate metastatic to bone 75 per cent in the authors series had elevated serum acid phosphatase readings when first seen. Nearly all (89%) had elevated serum alkaline readings as is to be expected from the almost universal osteoplastic character of the bone lesions secondary to prostatic cancer.

It sometimes happens that a patient with a normal or slightly elevated serum acid phosphatase has a tumor involving the prostate but ulcerating into the bladder or rectum, so that it is not possible by physical examination to determine the origin of the lesion. In such cases it may be possible to show whether the tumor does or does not originate in the prostate by measuring the acid phosphatase activity of extracts of tissue removed through the proctoscope or pan-endoscope. This possibility arises from the fact that the tissue acid phosphatase activities of carcinomas of the rectum or bladder do not exceed 3 units/gm. while that of prostatic carcinoma is usually greater than 100 units/gm.

Patients with carcinoma of the prostate experience prompt and striking clinical improvement following

surgical castration or estrogen therapy but 10 per cent of the carcinomas are completely refractory. When serum acid phosphatase is initially elevated it usually exhibits a marked drop within a week after surgical castration or within 2 to 3 weeks after the beginning of estrogen therapy. The alkaline phosphatase usually rises within a month after surgical castration occasionally after the beginning of estrogen therapy and when the clinical response is favorable the serum alkaline phosphatase falls again after 3 to 4 months. If clinical improvement is not maintained the alkaline phosphatase remains at high levels. After 4 to 6 months the serum alkaline phosphatase in castrated patients begins to reflect the clinical course rather closely. A similar response is seen much less frequently during the first few months of stilbestrol treatment.

DAVID ROSENBLUM, M.D.

Somalo M. Varicocele Due to Vascular Reflux; Operation of Ivanissevich; Origin Technical Derelopment and Present Status (Varicocele por reflujo operación de Ivanissevich. Origen Desarrollo técnico Estado actual) *Sem med B Air* 1946 53 948

In 1918 Ivanissevich advanced his conception of the common form of varicocele as the result of a venous reflux from the spermatic veins. When the blood in the veins is subjected to the intra-abdominal pressure it may overcome the resistance of the venous valvular structures and actually reverse its direction, passing down through the anterior bundle of veins (pampiniform plexus) which is contained within the fibrous tunic of the cord, into the tail of the epididymis. Here anastomoses pass to the posterior bundle which lies outside of the fibrous tunic of the cord. From this posterior bundle of the pampiniform plexus the blood runs off through the funicular and parietal systems of veins where the weight of the abdominal pressure is less noticeable. This is the order in which the varices develop and Ivanissevich has demonstrated this actual reflux in his early operations by cutting the spermatic vein at the internal inguinal ring under local anesthesia and having the patient bear down with his abdominal pressure, when the blood wells normally from the distal cut end but spurts across the operating room from the proximal end of the vein.

It was not until 1922 however, that he brought out his sign for distinguishing the reflux type of varicosities of the scrotum. With the patient lying down, the varicocele was milked back toward the abdomen and the venous supply therefrom pinched off at the base of the scrotum. The varicosities would remain empty even with the patient upright until the pressure at the base of the scrotum was removed. This is Ivanissevich's sign. Therefore, he taught and demonstrated that it is necessary only in the common type of varicocele to cut and tie off the spermatic vein or veins up high at the internal inguinal ring to effect a cure. At first the incision was made low over the inguinal canal and the in-

DAVID ROSENBLUM, M.D.

Somalo M: Varicocele Due to Vascular Reflux; Operation of Ivanisovich Origin Technical Development, and Present Status (Varicocele por reflujo operación de Ivanisovich. Origen Desarrollo técnico Estado actual) *Sem med* B. Air, 1946, 53 948

In 1918 Ivanisovich advanced his conception of the common form of varicocele as the result of a venous reflux from the spermatic veins. When the blood in the veins is subjected to the intra-abdominal pressure it may overcome the resistance of the venous valvular structures and actually reverse its direction passing down through the anterior bundle of veins (pampiniform plexus) which is contained within the fibrous tunic of the cord, into the tail of the epididymus. Here anastomoses pass to the posterior bundle which lies outside of the fibrous tunic of the cord. From this posterior bundle of the pampiniform plexus the blood runs off through the funicular and parietal systems of veins where the weight of the abdominal pressure is less noticeable. This is the order in which the varices develop and Ivanisovich has demonstrated this actual reflux in his early operations by cutting the spermatic vein at the internal inguinal ring under local anesthesia and having the patient bear down with his abdominal pressure, when the blood wells normally from the distal cut end but spurts across the operating room from the proximal end of the vein.

It was not until 1922 however, that he brought out his sign for distinguishing the reflux type of varicosities of the scrotum. With the patient lying down the varicocele was milked back toward the abdomen and the venous supply therefrom pinched off at the base of the scrotum. The varicosities would remain empty even with the patient upright, until the pressure at the base of the scrotum was removed. This is Ivanisovich's sign. Therefore he taught and demonstrated that it is necessary only in the common type of varicocele to cut and tie off the spermatic vein, or veins, up high at the internal inguinal ring to effect a cure. At first the incision was made low over the inguinal canal and the in-

guinal canal itself opened to ligate the vein at the internal ring. Later (about 1918) however the incision was placed higher and farther out beyond the inguinal canal and the vein sought, after the fascial and muscular coverings were cut through at a point further along before it became entangled with the other elements of the cord. This change in technique was not especially emphasized at the time and is one of the elements which has led to so much confusion about the Ivanisevich operation. However the basic concepts of the original Ivanisevich procedure have remained unchanged and any operation based on these concepts is merely a modification of the Ivanisevich operation.

Somalo's modification of the Ivanisevich operation consists merely in the location and character of the incision and the point at which the spermatic vein is reached. This point is on a transverse line drawn from the under side of the anterosuperior spine of the ilium, 6 cm. medially and about 3 cm. above Poupart's ligament. The skin is incised transversely over this point down to the fascial and muscular layers of the abdomen, which are then opened along the direction of the muscle fibers as in the McBurney gridiron incision. The spermatic vein can thus be reached in the space of Bogros beyond the point where the vessel was attained in the second operation of Ivanisevich.

JOHN W. BROWN, M.D.

Goodwin, W. E., and Vermooten, V.: Multiple Fibromas of Tunica Vaginalis Testis or a Proliferative Type of Chronic Periorchitis; A Report of 2 Cases. *J. Urol. Balt.*, 1946, 56, 439.

Two cases exhibiting multiple fibromas of the tunica vaginalis testis are reported in considerable detail. Both patients were white soldiers, 33 and 39 years of age. In the first patient the condition was discovered at the time of a routine examination and in the second patient it constituted the principal complaint. It is interesting to note that both patients presented some signs suggestive of arthritis.

The younger patient's tumor was found to originate from the tunica vaginalis and was distinctly separate from the epididymis. This was later confirmed by histological examination, which showed also some areas of calcification in the tumor. The second patient's tumor though originating from the tunica vaginalis, was intimately associated with the epididymis.

Histologically the significant picture of this grossly nodular mass is that of nodular fibrosis consisting of collagen without a distinct inflammatory reaction. The periphery shows a well developed capsule.

The paper embodies extremely good illustrations of both the gross specimens and cytological studies of the tumors.

ROBERT LACE, JR., M.D.

Da Fonseca, V. L.: Testicular Tumors (Tumores do testículo). *Arch. Brasil. Med.* 1946, 56, 375.

A case of seminoma of 6 months' duration in a 46 year old man is reported by the author who states

that according to the literature, neoplasms of the testes form 0.38 per cent of the total number of tumors occurring in the human body.

Traumas, syphilis, tuberculosis, heredity and sexual activity have been accused as etiologic factors. Of the various classifications the author chooses the simplest and the most practical one. This classification divides all testicular tumors into two groups: seminomas and teratomas. The propagation of metastases takes place chiefly through lymphatic paths, although mixed tumors may spread also through the blood vessels to form secondary tumors, chiefly in the lungs. Gynecomastia, frequently observed in patients with testicular tumors, has been attributed by various authors to atrophy of the specific testicular tissue, hyperfunction of the hypophysis, secretion by the neoplastic tissue of a hormone which is directly responsible for enlargement of the breasts, or finally to secretion by the tumor of a hormone which stimulates hypophyseal function.

Differential diagnosis must be made from hydrocele, hematocele, tuberculosis and syphilis.

Hormonal reactions are of great diagnostic value because the determination of the amount of gonadotropic hormones allows differentiation of various types of tumors. Such studies may even reveal the presence of metastases because the reactions are positive even after orchiectomy.

As to the treatment the author recommends a radical operation in the form of orchiectomy supplemented by extirpation of the lumbar and aortic lymph glands.

JOSEPH E. VASAT, M.D.

Vermooten, V.: Orchidopexy. *J. Urol.*, Balt. 1947, 57, 30.

Vermooten presents a new modification of the Bryan operation for orchidopexy. In the usual Bryan technique the testis is placed midway or at the upper end of the scrotum. The Torek operation must be done in 3 stages.

Vermooten believes that the scrotum, filled with elastic connective tissue fibers, must be incised from the inside until only skin is encountered, and that when the testis is simply placed against the elastic scrotal fibers the latter act as a hammock and tend to push the testis out of the scrotum. When adequate lengthening of the cord has been obtained at operation the only reason for the testis not to remain at the bottom of the scrotum is the normal hammock-like elasticity of the scrotum. Therefore, after lengthening the cord (dividing the vas deferens in a unilateral case if necessary) Vermooten divides the scrotal elastic fibers with a knife until only skin presents in the wound, and the testis is sutured against this denuded area. The sutures are tied on the outside of the scrotum and the testis is fixed automatically in the most dependent portion of the scrotum. Tension, by means of an elastic band, is then applied to the testis and scrotum by connecting the band to the medial aspect of the opposite thigh. Traction is maintained until the catgut suture sloughs out, usually on the seventh day.

The author believes that the good results of the Torek procedure are due not primarily to the placing of the testis in the thigh but that in this procedure the scrotal elastic fibers are divided

DAVID ROSENBLUM, M.D.

MISCELLANEOUS

Nesbit R. M. and Others: Effects of Blockade of the Autonomic Ganglia on the Bladder *J Urol Balt.* 1947 57 242

Teab (tetra-ethyl ammonium bromide) administered parenterally produces a blockade of the autonomic ganglia in animals and in man. The effects noted in man have been a fall in the arterial pressure, an increase in the heart rate, postural hypotension, an increase in the peripheral skin temperature, ptosis of the upper eyelids, loss of accommodation, dry mouth, decreased gastrointestinal motility, and difficulty in voiding. Further studies were undertaken by the authors to determine the effects of the drug on the urinary bladder and the act of micturition. From a consideration of the normal physiology of micturition it was postulated that the drug would (a) produce a blockade to the motor impulses being transmitted along the pelvic nerve in the region of the parasympathetic ganglia, which would result in impairment or complete absence of the voiding contraction of the bladder, (b) have no effect upon the temperature, the tactile proprioceptive, and pain sensations arising from the bladder, and (c) have no effect upon the ability of the bladder to adapt itself to increasing volumes of fluid at approximately the same intravesical pressure.

After ascertaining the residual urine, 60 c.c. of warm and cold distilled water were instilled into the bladder to determine the presence or absence of temperature sensation. Two cystometrograms were usually obtained for control before 500 mgm. of tetraethyl ammonium bromide were injected intravenously. During the cystometric procedures the patient was asked to indicate the time of first sensation of filling and first desire to void. If the patient did not void around the catheter when the bladder capacity had been attained, the catheter was removed and the patient was given a trial of voiding in the sitting position. Similar cystometrograms were obtained after injection of the drug.

Twelve of 16 normal patients showed a partial or complete response to the drug. A complete response

was arbitrarily designated as one in which the voiding contraction of the detrusor muscle was completely abolished and the patient was unable to void after the catheter was removed. A partial response denoted one in which the patient voided incompletely after injection of the drug and demonstrated a large residual urine, or one in which the bladder capacity was greatly increased. All of the 7 male patients showed a response to the drug, but in only 5 of the 9 female patients could a bladder response be elicited.

In 3 patients with autonomous neurogenic bladders (resulting from destruction of the motor and sensory roots of the spinal reflex arc controlling detrusor contractions) no changes in the cystometrographic findings were noted after administration of tetraethyl ammonium bromide.

In 4 of 5 patients with uninhibited neurogenic bladders (resulting from lesions of the cerebral motor cortex or the corticospinal tracts or from inadequate development of the normal integration of the cerebral inhibitory mechanism controlling voluntary micturition) both the uninhibited and voiding contractions of the detrusor muscle were abolished, and the uninhibited contractions were abolished in the fifth patient. All of the patients showed a tremendous increase in bladder capacity following injection of the drug.

Of 3 patients with reflex neurogenic bladders (resulting from a lesion of the spinal cord involving the afferent tracts carrying impulses to the higher centers, and the efferent tracts carrying inhibitory impulses from the higher centers to the lower motor neurons involved in the micturition spinal reflex arc, the arc itself being intact) 2 showed increased bladder capacities, but none of the 3 was able to void following the administration of tetraethyl ammonium bromide.

Of 3 patients with miscellaneous neurogenic bladder involvement which could not be classified in any of the previously mentioned categories 2 showed a bladder response similar to that seen in the reflex neurogenic bladder group.

Visceral sensation in all of the bladders was totally unaffected by the drug. The ability of the bladder to maintain an approximately constant intravesical pressure with varying volumes of fluid was not abolished by parenteral administration of the tetraethyl ammonium ion.

CLARENCE V. HOGGINS, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Mackenzie W.: Painful, Nonsuppurative, Localized Sclerosis of the Long Bones, with a Report of 2 Cases. *J Bone Surg* 947 29 49.

Sclerosing nonsuppurative osteomyelitis was described by Garré in 1892 before the roentgen ray was available. This condition has received roentgenographic recognition and is described by Gray as a rare form of chronic nonsuppurative osteomyelitis generally affecting either the tibia or femur in older children and young adults, which is characterized by a diffuse area of sclerosis near the end of the diaphysis, gradually fading off into normal bone.

Various writers have reported cases from time to time. In 1940 Jaffe and Lichtenstein described a series of such cases of which 13 involved the shaft cortex of long bones. The patients were adolescents or young adults. The principal complaint was pain, and it was this that consistently led the patients to seek medical attention. In no case was there a history of febrile episodes in connection with the lesion. Local heat and redness were absent.

Jaffe and Lichtenstein drew attention to 3 features in the roentgenographic appearance of these lesions (r) the focus (osteoid osteoma proper) which is generally indicated by an oval, relatively 'clear' area and (s) the surrounding osseous reaction incited in the adjacent bone when cortex of the long bone is involved, which results in very marked cortical thickening, which "may extend for several inches both above and below the osteoid osteoma proper" and may partially envelop the shaft of the bone.

These authors state "It seems very clear to us that a great many cases which have been interpreted specifically as osteomyelitis with annular sequestrum chronic bone abscess, osteomyelitis with cortical-bone abscess, 'sclerosing nonsuppurative osteomyelitis' osteomyelitis chronic from the beginning" etc., actually belong in the category of osteoid osteoma. Surgical treatment resulted in clinical cure "with prompt and often dramatic relief of distressing pain" there were no recurrences in 7 years.

It would appear that nonsuppurative sclerosis of the cortical bone, accompanied by pain, is a clinical and pathological entity for the explanation of which the associated existence of a benign neoplasm, designated "osteoid-osteoma," has been postulated by Jaffe and Lichtenstein, who further claim that the lesion admits of roentgenographic verification.

A completely satisfactory interpretation of the total lesion is not provided by the conception of reactive osteosclerosis in relation to a neoplastic center such as is described by Jaffe and Lichtenstein these authors indeed, admit that "why an osteoid-osteoma should arouse a perifocal osteosclerosis is by no means clear

The author reports 2 cases of painful, nonsuppurative, localized sclerosis of the long bones, one in a girl of about 11 years and the other in a boy of 14.

A special feature of these 2 cases is that the radiolucent area was not sharply outlined, resembling the illustrative roentgenograms of Jaffe and Lichtenstein and of others. On microscopic examination, the bone focus removed in the second case resembled the histological description given by Jaffe and Lichtenstein.

No positive opinion is expressed regarding the essential nature and cause of the bone lesion in the 2 cases.
ROBERT S. RICE, M.D.

De Pablo, J. S. and Caso L. S.: Multiple Exostoses (Las llamadas exostosis múltiples) *Congr. for Locomotor* 946 3 85

Multiple exostoses are known in the literature under a variety of names such as osteogenic disease, osteophytosis, osteochondrophytosis, cartilaginous perostosis and exostosis, osteogenic exostosis, hereditary deforming chondrodysplasia, and multiple osteochondromas. The condition is characterized by the presence of exostoses proximal to epiphyses, enlargement of metaphyses, curvatures of long bones, alterations of articular surfaces, synostoses, and rarefaction of the cancellous bone. It develops during the period of growth and occasionally shows a tendency to malignant degeneration. In some cases, hereditary factors seem to play a rôle.

As to the genesis of the condition, some authors have thought that the condition might be related to rickets, although no clinical or pathologic toxic findings lend support to this theory. Osteoid tissue and deficient calcification characterize rickets, while in exostoses only an irregularity of the ossification line, and/or a premature ossification of the epiphyseal cartilage may be found.

Another theory is that the condition develops as the result of exogenous toxic factors such as phosphorus, arsenic, or lead, or endogenous pathological conditions such as gout or diabetes, also acute infections such as typhoid fever or chronic infections such as syphilis or tuberculosis. The authors' observations did not lend any support to such hypotheses.

The supposedly more frequent occurrence of exostoses in the male sex is ascribed by some authors to traumas.

Endocrine disturbances such as a hypofunction of the thyroid gland have been considered a causal factor by some but in the authors' cases no metabolic changes could be detected. One school of thought suspects a pluriglandular insufficiency involving especially the hypophysis, thyroid, and genital glands.

The authors report their observations in 2 cases of multiple exostoses in males: one patient was 25

years of age, the other 40 years. In the first patient the hereditary factor was evident, the condition being transmitted from one generation to another by women. In reviewing the literature, the authors found no unanimity of opinion as to the greater prevalence of multiple exostoses in males.

The structure of exostoses varies according to the stage of evolution. In a fully developed specimen the following four layers, starting from the surface, may be distinguished: (1) fibrovascular sheath of perichondral type without any traces of ossification at the base of the exostosis the perichondrium merges with periosteum (2) cartilage (3) so-called ossiform tissue containing hypertrophic and calcified cartilaginous cells and fibrous bands with osteoblasts (4) osseous tissue, compact at the periphery and of medullary spongy appearance toward the center. The structure of osseous tissue is analogous to that of normal bones except that Haversian canals have a perpendicular direction to those in the adjacent normal bone. This is an important diagnostic sign because, in false exostoses of periosteal origin the Haversian canals are parallel to the bone from which they originate.

The growth of an exostosis stops when the ossification of the cartilage has been completed.

Absence of participation of the periosteum in the growth of the exostosis is characteristic, and this explains how spontaneous fractures of the pedicle of the exostosis may occur. Such fractures are due to a progressive rarefaction of the bone, and to muscular contractions without any compensatory activity of the periosteum. Occasional spontaneous disappearance of exostoses is attributable to the same condition.

Virchow believed that exostoses derive from a congenital displacement of cartilaginous tissue or a later expansion of the epiphysis. Other writers speak of an atavistic process and consider osteogenic exostoses as a reproduction of an ancestral type. Such a hypothesis is not applicable to cases with multiple exostoses. A teratologic theory is also unsatisfactory. Some authors consider a defect of periosteum responsible for the condition. There is histologic evidence of cessation of periosteal growth at the site of origin of exostoses. The fact that no periosteal lining can be demonstrated at the periphery of the exostosis also supports this theory. Under normal conditions the periosteal sheath and ossification of diaphysis take place simultaneously. If for some reason the advance of periosteum is retarded an excessive growth of the cartilage may take place.

The following processes are responsible for the ultimate structure of normal bone: (1) reabsorption (2) tubulation or transformation of metaphysis into diaphysis, (3) the formation of cancellous tissue (4) cellular division (5) cellular hypertrophy (6) cellular differentiation. A delay of reabsorption or tubulation of a part of the circumference of the bone may lead to formation of an exostosis.

Multiple exostosis may be responsible for pain caused by compression of adjacent tissues, especially

if the formation lies under a nail also for neuritis vascular alterations such as aneurysm, infection, stretching of tendons necessitating tenotomy and perforation into the urinary bladder and other organs.

The prognosis depends on the presence of complications especially malignant degeneration.

As a rule a complete extirpation is not followed by a recurrence. The presence of deformities may demand an osteotomy. JOSEPH K. NARAT, M.D.

Snapper I. Treatment of Multiple Myeloma. *J Am Med Ass* 1947 133 157

A series of 15 patients with multiple myeloma received stilbamidine combined with a diet low in animal protein and pentamidine (diamidine compounds). Good results, characterized by a notable influence on the pain, were obtained.

The dosage schedule of the stilbamidine which was given either intravenously or intramuscularly, and of the pentamidine is well described. To avoid a fall in blood pressure the author recommends the subcutaneous injection of 0.25 c.c. of a 1 in 2,000 solution of epinephrine 10 minutes before the injection of stilbamidine 1/150 to 1/300 of a grain of atropine sulfate is given to patients in whom sweating and dizziness are noticed. Dissociated anesthesia in the region of the trigeminal nerve is one late sign of intoxication.

The author gives a complete analysis of the results obtained and states that the disease is not cured but is checked temporarily. Three case reports are presented. GEORGE E. CLOUTIER, M.D.

Platt H.I. Survival in Bone Sarcoma. *J Bone Surg* 1947 29 6

Certain broad conclusions concerning the effectiveness of various methods of treatment of bone sarcoma are drawn from the Registry of the American College of Surgeons and from individual contributions by Coley, Campbell, Meyerding, Simmons, Macdonald and Budd.

Surgical eradication of accessible tumors is the treatment of choice. The value of postoperative treatment by means of irradiation or toxins seems to be still *sub judice*, but these therapeutic agents should not be withheld from a patient if circumstances permit their systematic use.

The outlook in the case of osteogenic sarcoma is not so gloomy as it appeared at one time. The spindle cell sarcoma (fibrosarcoma) appears to be the least malignant form. The opinions regarding the degree of malignancy of chondromyxosarcoma and extraskeletal sarcoma are conflicting. The prognosis in Ewing's tumor remains grave, despite its response to irradiation. Thirteen of the 14 patients who were recorded as having Ewing's tumors in the Registry report of 1939 survived for 5 years after treatment by surgical measures.

The author has submitted his collection of 161 cases of sarcoma. There were 23 cases with 5 year survival of which 22 were treated by radical opera-

tion and the survivals were fully proved. The other case a pelvic sarcoma, was not subjected to biopsy. Of 2 patients with pelvic sarcoma treated by hind quarter amputation, one lived 5 years and the other is still alive after 7 years. Eight patients in this series survived more than 10 years.

An attempt has been made to compare certain factors in the long survival cases with the same factors in a series of 40 short survival cases (under 3 years). No significance can be accorded to such factors as age, sex, site of tumor and duration of symptoms before the tumor was eradicated. Of 128 patients with accessible tumors which were treated radically, 70 patients survived more than 5 years, and 23 of these for 5 years or more. The author states that irradiation is admittedly a useless form of therapy in tumors of the osteogenic sarcoma type. In Ewing's tumor irradiation before amputation, or irradiation alone in accessible tumors, has no material influence on the ultimate fate of the victim of this most lethal type of bone tumor. DANIEL H. LEVITZKY, M.D.

Nielsen, B., and Snorrason, E.: Arthritis Mutilans. *Acta radiol. Stockh.*, 946 7 607

This report is based on 6 cases of chronic polyarthritides with marked mutilating osseous destruction found in the Bispebjerg Hospital, Copenhagen. It also includes a brief report of 7 cases from the literature.

Marie and Leri published the first case in 1913 under the title of Une variété rare de rhumatisme chronique la main en lorgnette. When the condition was confined to 1 finger these authors called it doigt en lorgnette. Weigelt reported a case in 1929 and Stursberg published a report of 2 cases in 1935. Werthmann reported a case in 1945. Schinz, Baensch, and Friedel reported a case but there were ulcerations which cast some doubt upon this classification. Helfink also reported some cases of doubtful classification.

All of the authors' cases were in women who had been suffering with polyarthritides for years. At a late stage they had all received sanocrysin therapy. There were striking destructive osseous changes in the metacarpophalangeal, metatarsophalangeal, and in the proximal interphalangeal joints. None of the cases revealed special features or complicating affections which might give a hint of the origin of the destruction, and none of the cases presented neuropathic disease or psoriasis. There was a mild anemia and elevated sedimentation rate. Laboratory investigation of the calcium and phosphorus metabolism was not made. Marie and Leri reported severe fatty degeneration of the bone and neighboring tissue. The spongy bone had disappeared and the compact bone was quite thin. There was granulation tissue between the bone ends which led the authors to believe that this was an inflammatory process. Reinhard, in Schueller's sixth case, described a condition resembling osteitis fibrosa. The nerves in that case were intact.

DANIEL H. LEVITZKY, M.D.

LaFerte, A. D.: The Role of the Platysma Muscle in Torticollis Deformity. *Plast. Reconstr. Surg.* 1947 3 73

The author believes that the platysma muscle becomes contracted in the torticollis deformity and that it should be freed laterally from the skin either by blunt dissection or by transverse section of the muscle to the extent of about 1 inch, at the same time that the origin of the sternocleidomastoid muscle is freed or a portion of the two heads excised.

He believes that the use of a skin incision parallel to, and between, the two heads of the sternocleidomastoid muscle permits passive and, later, active assistive exercises from 8 to 10 days after surgery since the pull on the skin is then not transverse to the healing incision. The author uses no cast or brace following surgery but applies bulky dressing, for the first 1 or 10 days, in such a way as to hold the head in a position of correction.

He re-emphasizes the difficulty of obtaining a satisfactory correction in older children because of the discomfort and strain entailed by readjustment of the eyes upon return of the head to its normal position. VERNON C. TUNNEY, M.D.

Maranzuela J.: Some Aspects of Volkmann's Ischemic Contracture (Algunos aspectos de la contractura isquémica de Volkmann). *Rev. esp. cir.* 945 8

Sudden suppression of the blood supply to an extremity produces anatomical and pathological alterations in a muscle. This is known as Volkmann's syndrome. Be it spasm, compression of a vessel between fragments of a fracture, or thrombosis of a vessel, the arterial flow is interrupted and asphyxia pulvix is produced which results in a muscular necrosis with replacement by fibrous tissue. This arterial block interrupts the blood supply to the nerves with nutrient vessels arising from the blocked vessel, and results in a paralysis. Even though the blood supply is re-established after from 6 to 8 hours, the damage is already permanent.

In the muscle one finds zones of muscular sequestra in which the muscle fibers may be identified, but their nuclei have disappeared, and they have lost all signs of vitality. Around the sequestra a leucocytic and fibroblastic barrier is formed, which in invading the zone of the lesion replaces the dead muscle by fibrous tissue and produces the contracture.

Nerve fiber regeneration is possible only when the nerve has suffered Wallerian degeneration. Regeneration is possible if an adequate blood flow is re-established. However the endoneurial collagenization and the necrosis resulting from lack of blood supply are irreversible lesions. Thus, loss of muscle function is due to loss of nerve supply.

Vascular obstruction may be determined by the nature of the pulse, oscillography, the temperature of the affected zone, arteriography and inspection of the vessels at operation.

Muscular lesions may be determined by physical examination, cutaneous electrical stimulation, elec-

tromyography injection of parabrodil in the affected muscle and observation of the absorption by roentgenographic observation

Nerve lesions may be determined by physical and neurological examination cutaneous electrical stimulation electromyography cutaneous temperature change inspection of the nerve and biopsy

Contractures may be avoided by the use of force in the reduction of fractures and by avoiding the use of improper casts and splints.

Within the first 6 to 8 hours the condition may be treated by the administration of oxygen injection of papaverine in the muscle immediate exploration of the artery with arterectomy if indicated to inhibit the spasmodic reflex effect on the collateral blood supply and incision of the fascia to relieve congestion

The actual treatment after the occurrence of the contracture is traction and hyperextension of the metacarpophalangeal articulation, while periarterial sympathectomy or resection of the fragment of the vessel, and infiltration of the ganglion with novocaine is helpful. The muscle may be lengthened by transverse myotomy although the author advocates Max Page's method modified by Mommson as being preferable while Henle advocates the shortening of bone

ARTHUR F. CROZILLA, M.D.

Shepherd J. A.: Constriction of the Extensor Pollicis Brevis Tendon. *Brit J Surg* 1946 34 313

Stenosing tenosynovitis (de Quervain's lesion) is a well recognized and fully documented condition, first described in 1895 (Scheidegger 1928). In adults it usually affects the extensor pollicis brevis or the abductor pollicis longus and in children it has been described as involving the flexor pollicis longus (Zandek 1942). In the common extensor type the patient complains of pain in the region of the radial styloid and of difficulty in straightening the thumb so that manipulation may be required. Passive movements meet with resistance and the thumb may extend with a definite "snap". Classically adduction at the wrist is free if the thumb is included with the fingers when this wrist movement is tested. There may be slight swelling over the affected tendon. The pathology tends to occur when the abductor pollicis longus and the extensor pollicis brevis pass beyond the osteofibrous canal overlying the lower end of the radius and on exposure a fibrous thickening of the tendon sheath is seen. This tissue is hard and cuts like gristle and it restricts the free play of an otherwise normal tendon. The histology suggests the remnant of trauma rather than infection, and certainly many cases occur in women using their hands with work. Treatment may be conservative or surgical. Immobilization may reduce the swelling of the sheath in an early stage of the condition. More satisfactory to the surgeon and patient alike is the operative exposure of the tendon under local anesthesia. The sheath is laid open and the free action of the thumb can at once be demonstrated.

Fig 1 (Shepherd) Diagram of the appearance on opening of the tendon sheath. The long limb of the occluding structure was detached from the roof of the sheath; the two short limbs were attached to the floor of sheath and the whole tendon. Note the groove in the tendon, from which the structure slipped off with a jerk. The top is the proximal part, the bottom, the distal part.

The author reported the case of a naval officer aged 42 who complained of pain in the right thumb. Preoperatively a diagnosis of de Quervain's lesion was made. With a pneumatic tourniquet on the upper arm, an incision was made along the line of the extensor pollicis brevis from the radial styloid 1 inch distally. A tendon sheath of normal thickness and consistency was exposed and slit open in the length of the incision to reveal the tendon tethered by a peculiar band of tissue. The paired limbs of the structure arose from the floor of the sheath on each side of the tendon and embraced the latter tightly over the volar aspect—tightly enough to cause a local constriction of the tendon. On extension of the thumb the band jumped out of the groove it had printed on the tendon—the intermittent symptoms were thus readily explained. The obstruction was excised by dividing it at the three attachments to the sheath. A probe was passed distally for an inch but no further obstruction was encountered. The extensor pollicis brevis may share a common canal with the abductor pollicis longus at this point but in this case the tendons had separate compartments. It was considered wise to inspect the adjacent sheath but on slitting it open no abnormality was found. The abductor sheath was approximated with 5 fine catgut sutures the abnormal sheath was left open. The skin was closed with silk sutures.

Postoperatively the patient was free from all symptoms. It was believed that a congenital origin for the condition was most likely.

C. FRED GOINGBARGER, M.D.

Moulouquet P., Delannoy E., and Drieschner: Giant Cell Tumor of the Femoral Neck Treated Surgically and with X rays. Fatal Evolution of Sarcoma of the Pelvis (Tumeur à myélopaves d'os fémoral traitée par chirurgie et rayons X. Évolution mortelle d'un sarcome de bassin) *Année chir. Fr.* 946 72 556

A giant cell tumor of the left femur in a 23 year old woman was recognized when a spontaneous fracture occurred. Curettage and bone graft followed by intensive x ray therapy were employed after a preliminary traction with Kirschner wire for 8 days to obtain reduction. Reparative processes were slow and insignificant and 14 months after the operation a new osteolytic phase appeared. A new bone graft was placed and the patient felt relatively well after that operation, but 7 months later the pain reappeared and tumor masses in the left ischium and the rest of the pelvis. The patient succumbed to her condition before an interilioabdominal amputation could be performed.

The authors consider their observation as an example of the transformation of a giant cell tumor into a malignant neoplasm. Another hypothesis may be considered namely the development of a pelvic sarcoma in the vicinity of but independent from the giant cell tumor of the femur. It should be remembered that the irradiation of osseous tissues may induce the development of an osteogenic sarcoma, and because of this it has been suggested that instead of heavy cytolytic doses of x ray only smaller doses (such as are used in the treatment of infectious lesions) be employed in the therapy of giant cell bone tumors. JOSEPH E. NARAT, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Murray A. R.: Reconstructive Surgery of the Hand. *Br. J. Surg.* 946 34 3

This article deals with three main methods of reconstruction of the severely damaged hand: (1) the transposition of one of the remaining digits of the same hand (transposition of the index finger to make a thumb); (2) a whole finger graft from the other hand (a toe has been used quite successfully, but a finger gives a better functional result); and (3) the man's manufacture of an artificial finger from living tissue.

The essential anatomical structures which subserve the basic function of the hand are two digits capable of being brought into apposition with each other. In other words, a thumb and one finger. Functionally there is little to choose between a hand without fingers and one that has lost the thumb.

The author has attempted arthroplasties of the digits with metal hinges.

Six cases are described as illustrations of the three methods of reconstruction.

This type of surgery is most difficult and the end results described warrant thorough study of the methods by anyone contemplating reconstruction of the crippled hand. VICTOR C. TURNER, M.D.

Fowler S. B.: Mobilization of the Metacarpophalangeal Joints. Arthroplasty and Capsulotomy. *J. B. & Surg.* 947 29 93

A series of cases presenting destruction of one or both joint surfaces of the metacarpophalangeal articulations is presented.

Arthroplasty is indicated in such joints if there is less than 30 degrees of motion in a useful arc, and if mobilization will restore a practical degree of function to the digit. The technique is as follows:

An incision 5 cm. long is made over the dorsolateral aspect of the joint, and the joint is exposed through the space between the interosseous and extensor tendons. A joint space of about 1 cm. is obtained largely at the expense of the proximal phalanx, which is cut transversely. The metacarpal head is bevelled off dorsally (Fig. 1). An interposition membrane, composed of the fascia overlying the fasciculi of the distal one-third of the thigh is meticulously applied to both joint surfaces. If there has been a loss of intrinsic muscle substance or marked shortening of the metacarpal, it is important to transfer the flexor digitorum sublimis tendon into the lateral bands of the extensor aponeurosis. A cast is applied and traction with the joint at 60 degrees of flexion is used postoperatively. Exercises are begun in 7 days and the cast is removed for further exercises in 3 weeks. A removable splint which flexes the joint is applied if there is incomplete flexion up to an additional 2 months.

The author regards the metacarpophalangeal joints as the most favorable in the body for arthroplasty. The results in his 13 patients appear to have been generally good, but detailed case reports are not presented.

Capsulotomy is advised for stiff metacarpophalangeal joints when the joint surfaces are intact and when physical therapy has failed. The operation will fail if any factor necessitates extension of the finger immediately following surgery. The extensor tendons must be free and allow complete flexion. Extreme caution must be exercised if a capsulotomy is done on a hand with circulatory insufficiency for gangrene of the fingers may result. Simple removal of the collateral ligaments, which are adherent to the surface of the metacarpal head, will not restore normal motion because the gliding of the phalanx around the metacarpal head will not occur.

The technique of capsulotomy is as follows:

An incision 1.5 cm. long is made on the dorsal aspect on both sides of the affected joint. The collateral ligament is completely removed on both sides of the joint. If the extensor tendon is adherent to scar tissue, the interphalangeal joints will extend when the metacarpophalangeal joint is flexed. It must be freed. If the phalanx does not glide around the metacarpal head, the capsule must be stripped from the head either by forcible flexion or by use of a blunt dissecting probe. If the extensor tendon subluxates to the side of the joint when it is flexed this must be corrected by section of part of the lateral expansion of the tendon on the side of the subluxation, or by

Fig. 1 (Fowler) Arthroplasty of the metacarpophalangeal joint. Left, Proximal phalanx severed transversely

Metacarpal tapered on flat. Right, Fascia with weblike consistency used between joints.

tightening of the opposite side. Postoperative splinting or traction to keep the joints flexed is necessary. After 3 weeks a removable splint is applied for a month or longer if the deformity tends to recur. From 80 to 90 degrees of motion are to be expected following capsulotomy but imperfect results occur if surgery is improperly done or if other factors remain in the hand which render proper use of the joint impossible.

NEWTON C. MEAD, M.D.

shaped with reamers care being taken to sacrifice a minimum amount of bone the mold is applied and the greater trochanter is introduced into the acetabulum. The divided muscles are transplanted to the infratrochanteric region and fastened by heavy silk sutures or by wire.

4. Intertrochanteric mold arthroplasty was employed in cases in which the greater trochanter was so atrophied that it could not be shaped and used for a modified Colonna operation.

Law described the postoperative results in the series of 42 cases which he assessed by clinical and roentgenographic examinations while attempting to determine the value of the operation both to the patient and to the surgeon.

Pain is minimal in the majority of the cases. Mobility of the hip joint is considered in conjunction with stability. The great majority of the patients are able to dress themselves sit in low chairs for protracted periods, and to perform their ordinary household and social activities. Gait is dependent upon strict training and muscle re-education with particular attention to heel toe movement. Residual deformity is minimal in patients treated by the routine mold arthroplasty and is more marked after the Colonna and intertrochanteric arthroplasty procedures. The following conclusions have been drawn from this study:

1. Eighty five per cent of the results are satisfactory to both patient and surgeon.
2. There is progressive improvement in function for 3 or 4 years after operation. The condition then becomes stationary. (The postoperative period in the oldest case is now 7½ years)
3. In this series of patients low back symptoms stiff knees, or postural difficulties were not present.

Fett, H. C., O'Connor J. J. and Johnson, J. A. Experiences in the Treatment of Traumatic Cavitation in the Upper Tibia. *Am J Surg* 1947 73 11

After reviewing much of the literature on the management of compound fractures involving gross

Smith Petersen M. N. Larson C. B. Aufranc, O. E. and Law W. A.: Complications of Old Fractures of the Neck of the Femur. Results of Treatment by Vitallium Mold Arthroplasty. *J Bone Surg* 1947 29 41

Mold arthroplasty consists in first creating a joint as nearly perfect mechanically as possible, and then guiding nature's repair by means of an inert mold and carefully supervised exercises. As applied to the treatment of complications of fractures of the femoral neck, the procedure is varied according to the extent of the degenerative changes.

1. In aseptic necrosis of the head, limited in extent and occurring after union of the fractured neck a routine mold arthroplasty is indicated. This consists in reshaping the head and acetabulum so as to create two congruous surfaces. The crater representing the necrotic area is excised down to bleeding bone and, in cases of relatively extensive necrosis the resulting defect is packed with cancellous bone from the iliac crest. The reshaped femoral head is covered with a vitallium mold and replaced.

2. When the aseptic necrosis involves most of the head, even though the fracture has united a modified Whitman reconstruction operation is indicated. This consists in discarding the dead head, reshaping the viable remaining neck covering it with a vitallium mold, and replacing it in the acetabulum.

3. In nonunion with a dead head and more or less complete absorption of the neck, a "modified Colonna" operation is indicated. This consists in creating a deep acetabulum and freeing all muscle attachments from the greater trochanter down to the infratrochanteric region. After the trochanter has been

tissue loss, the authors present 7 cases of cavitation in the proximal tibia. The article is complete with photographs and roentgenograms. All of the patients had compound fractures of the tibia and fibula and 5 patients had peroneal nerve paralysis. Since the loss of substance (both bone and soft tissue) was already extensive, and the tibial articular surface was involved, classic saucerization would have jeopardized the integrity of the tibial plateau still further.

Sequestrectomy with elimination of spurs overhanging bone edges and infected bone, was carried out, but saucerization was done only in the distal portion of the wound and to an extent that did not threaten the architectural integrity of the tibia. All limbs were immobilized in plaster and in 4 cases pin traction in addition was used, but osteomyelitis about the pins necessitated their early removal. Chemotherapy was indicated and used both locally and systemically, and in 3 cases amputation was rendered unnecessary, by the use of penicillin.

The use of antibacterials in the wounds was purely for the purpose of promoting clean, healthy granulations and rapid epithelization. *Bacillus proteus* was rapidly eliminated by the use of 1 per cent acetic acid soaks. *Permease* was found to be unsatisfactory and sulfonamides valueless in local treatment. Tyrothricin and penicillin were the most effective local agents. Aseptic technique was employed in all changes of dressing.

Weight bearing in cast or brace was begun as early as 2 to 3 weeks and clinical findings permitted, and the authors state that all patients are now active without braces, although all have limitation of knee motion. Epithelization is complete in all but 2 and any reconstructive procedures, bone or soft tissue, are considered inadvisable lest latent infection be reactivated.

FRACTURES AND DISLOCATIONS

H. Ros Codorniu A.: Fractures and Dislocations of the Elbow (El codo: sus fracturas y luxaciones) *Ciruj. por locomotor* 945

The author has written in Spanish an extensive and well illustrated monograph on fractures and dislocations of the elbow. The book is divided in 20 chapters which review the phylogenesis, anatomy, mechanics and general exploration of the elbow. The various types of fractures and their management are considered in great detail. The post-traumatic ossification, and the neurological complications in the elbow are also discussed extensively.

The presentation of this study is very well organized and its value is enhanced by very beautiful illustrations of all types. WILLIAM E. RICHARDS, M.D.

Stanger J. K.: Fracture Dislocation of the Thoracolumbar Spine, with Special Reference to Reduction by Open and Closed Operations. *J Bone Surg* 947 29 07

This article is based upon an analysis of 43 patients treated at the Royal Victoria Infirmary during a

period of approximately 6 years. In the district served by this hospital a great many serious industrial accidents occur especially in coal mines. At this hospital the indications for operation in fracture dislocation of the spine are

- 1 Section of the cord
- 2 Pressure on or stretching of the cord without section
- 3 Hematomyelia or edema

Unless the paraplegia is partial, it is impossible to tell whether or not there has been a complete severance of the cord. When paraplegia is not present in cases of fracture dislocation the complete correction of the skeletal lesion is indicated so that a maximum recovery of function will occur.

A closed reduction was attempted on 3 patients with complete paraplegia. There is a higher incidence of paraplegia at the thoracolumbar junction than in the lower lumbar region. The extent of skeletal damage is no indication of the degree of cord trauma. A simple interlocking of the articular facets in the thoracolumbar region with a minimum shift is often associated with complete paraplegia. The method of reduction seems to play little or no part in the possibility of recovery. In this series of 43 cases closed reductions appeared to give better results than open ones.

In the lower lumbar region, gross displacement may be present without paraplegia. The early appearance of the first signs of recovery of sensation or of motor power is no indication of the prognosis.

Hyperextension without anesthesia resulted in reducing the fracture dislocation in 1 case.

McLaughlin H. L.: Adjustable Internal Fixation Element for the Hips. *Am J Surg* 947 73 50

Rigid and accurately fitted internal fixation is the method of choice for managing fractures about the hip, as well as for reconstructing the upper femur in certain cases. The devices in use have a proximal part which is driven into the femoral neck and head, and a distal part which is fixed to the femoral shaft by screws. All the devices present certain limitations; they may be difficult to apply or fail to provide secure fixation. It is desirable that there be range of nail or blade lengths as well as of the angle at the junction of the two components, which in no way compromises their structural integrity.

One or both of these desiderata are wanting in the devices heretofore available. The axis of the femoral shaft must be shifted to coincide with that of the plate if the proximal arm is not introduced into the trochanter at exactly the optimum angle. The uneven distribution of strain thus created jeopardizes the maintenance of position and the security of fixation. If the nail is too long, collapse of cancellous bone during bearing may result in protrusion into the acetabulum.

The Fracture Service of the Presbyterian Hospital, New York, has developed a mechanism which fulfills all these requirements. A hemispherical head

Fig. 2

Fig. 2 Side view of the adjustable instrument in cross section. A, Nail and plate are fastened together by a heavy set screw passing through a slot in the curved upper portion of the plate to engage 5 full threads in the head of the nail. B Inset shows an enlarged drawing of the locking mechanism.

Fig. 3

Fig. 3 The apposing hemispherical surfaces of nail and plate are buried in such a way as to assure reciprocity regardless of variations in the angle between the two. Tightening of the set screw locks these reciprocal surfaces together in the desired position.

Fig. 3. Front view of the instrument. The plate may be rotated around the center of the axis formed by the set screw to conform to variations in flexion or extension of the femoral shaft.

is buried on a Smith Petersen nail to fit an identically curved surface on the proximal end of a plate. The longitudinal slot in the curved surface of the plate permits accurate locking of the plate and nail at any angle between 120 and 160 degrees by a heavy set screw which engages 5 full threads in the nail head. The plate may be rotated on the axis of the set screw a full 360 degrees. Nails are available in all lengths, and plates are used mostly in the 5 and 7 inch lengths.

Exposure through the interval between the tensor fascia femoris and the lesser gluteus muscles is most satisfactory. To avoid the subgluteal dead space created when the maximus muscle falls back the deep tensor fascia is incised separately from the superficial fascia and so that its posterior segment remains as a sling to hold the maximus in normal position. Fascial closure without tension is facilitated.

The type of fixation described causes an appreciable bulge of metal from the shaft of the femur so that snug fascial closure is desirable. No subjective symptoms have appeared in spite of this readily palpable projection.

Details of the technique of inserting and locking the nail and plate are important in securing solid fixation. Because of the tendency of fractured cancellous bone to collapse the point of the nail should penetrate not closer than 1.5 cm. to the acetabulum to allow for this settling and to prevent penetration to the joint surface.

FRANCIS E. BRIDGEMAN, M.D.

Kleinberg S.: Recurrent Dislocation of the Patella. *Bull Hosp Joint Dis* N Y 1946 7 141

Recurrent dislocation of the patella is due to abnormal laxity of the supporting tissues which allows displacement of the patella upon or to the outer side of the external condyle. The following etiological factors were found to be responsible for recurrent dislocation of the patella in a series of 35 patients operated upon in the author's hospital since 1936.

1. Knock knees in which the pull of the quadriceps tends to dislocate the patella.

2. Defective development of the lateral femoral condyle. Here the barrier to lateral displacement of the patella is lost.

3. Imperfect development of the patella: the articular surfaces of the patella form a less acute angle than normally.

4. Laxity of the capsule and patellar expansion on the inner aspect of the knee.

5. Abnormal length of the patellar ligament allowing excessive mobility of the patella.

6. Trauma severe enough to cause dislocation of the patella in a normal knee.

Recurrent dislocation of the patella usually occurs for the first time in childhood or early adolescence. Recurrence of dislocation of the patella may then follow minor incidents like stepping off a curb, turning while dancing, sudden straightening of the knee.

The subjective complaints are characterized by a sense of weakness in the affected knee. Reduction of the dislocation can usually be accomplished with

case by the patient or the surgeon. The first incident of dislocation usually is followed by swelling and pain lasting for a few days. Subsequent dislocations may not be associated with any discomfort or loss of motion. In some instances, especially in dislocations following severe trauma, reduction can be accomplished only by surgery.

Röntgenograms of the patella taken in an infero-superior direction with the patient in a prone position and the knee flexed to 70 degrees are helpful in the study of the bony structures with regard to recurrent dislocation of the patella.

Operative repair is the treatment of choice. Operations devised for the repair of recurrent dislocations of the patella generally aim to correct a manifest bony deformity, i.e. osteotomy of the femur or bones of the lower leg for knock knees or elevation of the congenitally underdeveloped lateral femoral condyle (Brackett-Albee). The purpose of the operative procedure may be designed to change the direction of pull of the patellar ligament, i.e. transfer of the insertion of a portion of the patellar ligament to a more medial position on the tibia (Goldthwait) or transplantation of the patellar ligament with a block of bone to a more medial position on the tibia (Hauser). The operation may seek to diminish the slack of the soft tissues on the inner aspect of the knee, i.e., excision of a fragment from the inner capsule of the knee and reefing of the cut edges (Krogh). Finally, it may be the aim of the operation to establish a check against outward displacement of the patella, i.e., suture of a strip of tissue of the lateral aspect of the capsule to the medial femoral condyle (Campbell) or anchoring of the patella to the medial condyle of the tibia by using a strip of iliotibial band (Ober) or fascia lata (Soutter-Gallie).

The reported results of all these procedures have been good. The author presents 6 cases of recurrent dislocation of the patella in detail. The Goldthwait type of repair was used in every case with or without reefing of the inner capsule of the affected knee. The patients were re-examined up to 3 years after the operation and were found to have had no recurrence of the dislocation of the patella and had full and painless range of motion.

GROVER I. REED, M.D.

Denis, R.: Bone Grafting. I Pseudarthroses and Recent Fractures of the Tibia (L'ostéogénèse par éclissage à l'os purum dans les pseudarthroses et les fractures récentes du tibia). *Rev. chi.* Par 946 65 3

The use of the bone grafting method described in this article was started by the author in 1929. At that time a rectangularly shaped graft was taken from the healthy tibia and placed in a trough cut longitudinally across the fracture line of the affected tibia. The graft was fixed with pegs made out of living bone. This procedure was long and tiresome but it appeared to be the operation of choice for repair of pseudarthroses of the tibia. Then Orrell reported his work with os purum and heterogeneous

grafts prepared from beef bone treated with potash and acetone until it was free of albumin, fat, and connective tissue. Orrell stated that these grafts were very well tolerated and that the os purum had osteogenic qualities. The os purum was prepared on a large scale by a Swedish concern. The grafts were available in any size and shape and were cut accurately to the millimeter. They were firm and gave rigid fixation to the bone. There was no need to take grafts from the healthy bone which simplified the procedure considerably. A standard procedure was followed.

Reduction of the fracture was done as accurately as possible sometimes with the use of the fracture table. Two holes were drilled in the bone (5 mm. in diameter) 58 mm. above and 58 mm. below the fracture site. These 2 holes penetrated into the medullary cavity and lay in the longitudinal axis of the bone. They were then connected by a channel made with a double blade electric saw. The channel was made 120 mm. long and 5 mm. deep. Since the graft had to fit tightly into the channel the walls of the trough had to be even and smooth. It was also important to level the bottom of the channel since the graft fitted into it. A specially designed instrument (*raise de fond-rasp*) was used for this purpose.

The os purum, which measured 20 by 5 by 35 mm. was sterilized by boiling and inserted into the prepared trough by means of slight blows of a mallet. It was fixed in place with stainless steel screws. The anterolateral aspect of the tibia is freed by dissecting away the anterior tibial muscle for a length of 15 cm. and a width of 12 mm. Four holes 3 mm. in diameter were made into the tibia perpendicular to the graft. Four specially designed screws were used and tightened in place with the help of a screwdriver designed after the one used in the mirror trade. The excess of graft extending above the tibial surface was removed with a saw with an oscillating blade. Excellent results are obtained by observing the following points:

1. Firm pressure of the bone fragment upon one another.
2. Firm immobilization.
3. Strict aseptic technique. It is a mistake to believe that the aseptic technique was satisfactory just because there was no abscess formation.

The tarnishing of screws, a zone of rarefaction around the graft, and the formation of fibrous tissue around the plate are due to latent infection and not to foreign body reaction. Sharp dissection with the scalpel or scissors (never with a sponge) perfect hemostasis, avoidance of the denudation of bone and dead spaces, drainage of the wound for 24 hours postoperatively, and a "no touch" technique are very important factors in carrying out this procedure.

Pseudarthroses are the most important indications for this bone-grafting procedure. The fracture site is not excised unless the fragments are badly displaced and cannot be reduced by any other means.

The fibrous tissue that lies between the bone ends ossifies if firm fixation is maintained

In spite of Orrell's assurances of the osteogenic qualities of the os purum graft the authors were very skeptical but clinical experiences support all his statements. The osteogenic qualities of the os purum resist a certain amount of infection and persist even after the graft is removed.

An area of rarefaction around the graft indicates that there is pus around the graft. In spite of the infection around the graft it is left *in situ* until there is evidence that union has begun to form. The removal of the graft will not interfere with further consolidation. Pseudarthroses following an old compound fracture or an operation are no contraindication to the use of os purum as bone grafting material. Its place in the treatment of recent fractures is limited.

The authors have used the os purum in 27 cases (among more than 1,000 bone grafting operations). There were three groups.

The first group included infected fractures which showed fibrous union at the time of operation. The grafting operation was done from 9 days to 3½ years after the accident.

The second group consisted of fractures in which pseudarthroses followed delayed union after orthopedic surgery and bone grafting operations.

The third group included simple fractures of the tibia which were grafted immediately after the accident.

There were 11 patients in the first group. In 9 cases a curettage was done as a preliminary procedure and in 2 cases a bone grafting operation was done prior to the os purum operation. There were 10 cases of postoperative infection. In 7 cases there was no sign of incorporation of the grafts after a period of from 2 to 10 years respectively. There were 2 partial incorporations of the grafts after 8 years and 1 complete consolidation after 5 years; there was 1 amputation. There was bony union in 10 cases. The result was classified as very good in 4 cases, good in 6 cases and fair in 1 case.

There were 10 cases in the second group. In 5 cases there were bone grafting operations or other orthopedic operations which were done prior to the os purum operation. The os purum grafting operations were done from 2 to 8 months after the accident. There were no postoperative infections. There was complete incorporation of the graft in all of the cases. There was union in every case without shortening or deformity. The results were classified as very good after follow ups of from 2 to 11 years.

There were 6 cases in the third group. Four cases with diaphyseal fractures became infected and did not tolerate the graft. The 2 others metaphyseal fractures healed per primam and incorporated the graft. There was eventual union in all cases without shortening or deformity. One result was classified as very good after 9 years, 4 results as probably very good after follow ups of from 12 to 15 months and 1 result as questionable after 3 months.

In conclusion the author states that the os purum graft is preferable to inlay and intramedullary grafts. He cites the following points:

The inlay graft although easily applied, gives in sufficient fixation, while the intramedullary graft requires a mutilating operation. The pseudarthrosis must be resected, which results in shortening of the part and in sacrifice of readily ossifiable tissue. The immobilizing qualities of an intramedullary graft are not satisfactory. The intramedullary graft cannot very easily be removed should infection warrant it.

Failures of os purum grafting are due to faulty technique or inadequate fixation. The os purum is more resistant to infection than fresh bone. The osteogenic power of the graft has not been overestimated by its discoverer as shown by clinical and roentgenographic control in the author's cases. There were no histological studies made.

An os purum graft is preferable to an autogenous graft or bone plating in the following cases:

1. In pseudarthroses and noninfected delayed unions, i.e., old simple fractures or old compound fractures which do not show clinical infection.

2. Pseudarthroses following previously infected fractures with scar formation in the soft tissues and skin. The persistence of a fistula does not constitute an absolute contraindication. Penicillin does not help much in these conditions. In doing the os purum grafting operation one must be prepared to remove the graft as soon as union is seen on x-ray examination.

3. Recent simple fractures in the metaphyseal portion of the tibia where bone plating will not give sufficient immobilization. The femur, humerus, radius and ulna may tolerate large metal plates well, but the tibia does not tolerate them because of the proximity of the skin. GAZDAR I REZAS, M.D.

D. Aubigné, R. M., and Denhart: The Treatment of Malunited Fractures of the Ankle (Traitement des cas vicieux du cou-de-pied). *J. chi., Par.*, 1946 62: 365.

Malunited fractures of the ankle mortise are difficult problems in orthopedic surgery. No article dealing with this problem was published since the last French Orthopedic Congress in 1938 yet the interest in this problem has persisted. Malunion of the ankle mortise was treated in 24 cases. The results were compared with those published in the Anglo-American literature accessible to the authors after the liberation.

The cardinal symptom of malunited fractures of the ankle joint is pain. There is a mechanical reason for the pain. The astragalus which transmits the weight to the foot is malaligned which causes either a flatfoot with a valgus deformity or an equinus deformity with posterior subluxation. Walking on such a deformity results in tearing of the ligaments, pressure sequelae, and pain. The pain is located in the tibioastragalar joint but also secondarily in the subtalar, tarsal, and tarsometatarsal joints.

This fact is well demonstrated by residual pain in the joints of the foot even after successful fusion of the ankle joint in a deformed position. If the deformity is corrected, the pain ceases. Degenerative arthritis is the other factor responsible for pain in the ankle joint and has to be taken into consideration when the indications for operation are evaluated. Necrosis of the articular cartilage occurs either because of malalignment or extension of the fracture to the joint surface and gives rise to exostoses and pathological calcification. There is also diffuse osteoporosis of the affected region. Trophic and arthritic disturbances of the bones are associated with similar disturbances of the soft parts, i.e. edema, cyanosis, pigmentation of the skin, and atrophy of the muscles. The changes in the soft parts disappear after fusion of the affected joint is accomplished.

Fusion of the ankle joint very rarely occurs spontaneously. Arthrodesis is a very valuable operation in the treatment of malunited fractures of the ankle joint. In a series of 48 cases (Halford and Hullock) degenerative arthritis was found in the ankle joint in 15 cases, in the subastragalar joint in 7, in the naviculocuneiform joint in 4, and in the distal tarsal joint in 1 case; the rest of the cases showed malunion without concomitant arthritis.

The surgical treatment of the malunited fractures of the ankle has two aims: (1) the re-establishment of normal transmission of the body weight from the leg to the foot, and (2) whenever possible, the preservation of motion in the tibioastragalar joint. In cases of partial ankylosis of the ankle joint no attempt should be made to preserve motion but ankylosis should be encouraged.

There are five operative procedures used in the repair of malunited fractures of the ankle joint: resection of the tibiotarsal joint, astragalectomy, osteotomy at the malunion site, supramalleolar osteotomy, and arthrodesis of the ankle joint. The plastic resection of Syme is impractical and always has had poor results in the hands of the authors. Astragalectomy cannot be justified in the light of theoretical considerations or of the results. It is well known that incongruity of the astragalus in its mortise is followed by arthritis and pain. More pain and arthritis is therefore to be expected if the tibia is placed on the calcaneus. Polleux reports the end results in 7 cases of astragalectomy: a cases required further operative repair; 1 result was very poor; 3 results were fair; and 1 result was good but the patient had to wear an orthopedic shoe. Pain is due to displacement of the bones in the nearthrosis. Ollier pointed out that there is often varus deformity in these cases with ulcer formation on the outer aspect of the foot. Ankylosis of the ankle joint in a right angle is preferable to ankylosis after astragalectomy.

The present report is based on a series of 26 of malunited fractures of the ankle. The cases are put into four categories:

- Valgus deformity
- Valgus deformity with posterior subluxation of the astragalus

c. Varus deformity

d. Anterior subluxation

Osteotomy at the malunion site. This procedure was done in 13 cases of which 10 were followed up for a long time; the results were classified as excellent in 4 cases, good in 1 case, and bad in 1 case. In the last patient the deformity recurred. All patients had valgus deformity with tibiofibular diastasis; in 3 cases there was a posterior tibial marginal fragment without displacement, and in another 2 there was posterior subluxation. At least two-thirds of the roof of the ankle mortise was preserved in all of the cases. Osteotomy at the site of the deformity is indicated in cases of malunited fractures of the ankle with valgus deformity and in which at least two-thirds of the articulating surface of the roof of the mortise is intact.

Supramalleolar osteotomy. In this operation a wedge osteotomy is done with the base of the wedge directed toward the concavity of the deformity. In 1 case a linear rotation osteotomy was done. In this case there was union of the fracture and rotation of the lower fragment, but with maintenance of the longitudinal axis. The result was satisfactory.

The supramalleolar osteotomy is done in cases in which the deformity is located in the malleolar region. There were 14 patients subjected to operation and followed up for a long time; the results in 13 in which malunion and ankle fusion followed supramalleolar osteotomy of the ankle joint were classified as excellent. In 6 cases there was some motion in the ankle joint which was worth saving. In 1 of these cases a shortening of the fibula had to be done at the same time. It was followed by a excellent result. The remaining cases presented valgus and varus deformities with a slight degree of posterior subluxation. There were 2 failures in which there was some degenerative arthritis; these 2 cases should have been treated by arthrodesis instead. It is important to keep in mind that in doing the osteotomy 1 or 2 cm. above the ankle joint the blood supply to the articulating cartilage may be impaired and this will be followed by cartilage degeneration.

Supramalleolar osteotomy is indicated in cases in which there is malunion with perfect tibioastragalar articulation. When in doubt arthrodesis is done.

Ankylosis operations. The fear that ankylosis of the ankle joint will severely interfere with normal locomotion is utterly unfounded. In fact, ankylosis is preferable to limited motion in the ankle joint. In the absence of pain the subastragalar and distal tarsal joints compensate for the lack of motion in the ankle joint. It is very important to obtain fusion in a favorable position and have good alignment of the foot in relation to the leg. Generally there are two procedures: simple fusion of the ankle joint with a wedge osteotomy of the wedge on the astragalus. It is not at all a long immobilization.

fusion in the ankle joint is designed to eliminate arthrodesis associated with the latter procedure in the tibia and hall

fusion in the ankle joint is designed to eliminate arthrodesis associated with the latter procedure in the tibia and hall

Fig. 1 (D'Aubigné Denisart) The osteotomies should permit perfect reduction of the external displacement. The medial malleolus is osteotomized just proximal to the callus formation. Osteotomy of the outer malleolus allows lengthening of the bone at the end of the procedure.

Fig. 2 The technique of supramalleolar osteotomy. A, Outline of the wedge to be removed. B, Correction after osteotomy. Preferably the osteotomy is done a little higher up. C, The plans of osteotomy diagrammatically demonstrating the use of the narrow bladed saw of Farabeuf.

walking was resumed too early fusion failed to occur and pain persisted.

All old malunited fractures of the ankle should be operated on if pain persists even if the displacement is only slight. Often slight tibiofibular diastasis is very painful and therefore disabling.

The three most commonly used operations are described in detail.

Osteotomy at the malunion site. Two incisions are made, one over the lateral aspect of the ankle and the other over the medial aspect. The osteotomy of the medial malleolus is somewhat above and parallel with the fracture line and is directed toward the angle formed by the roof and the medial wall of the ankle mortise. Osteotomy of the fibula is done on a slightly higher level. The tibiofibular ligament is then severed. The ankle mortise is molded into shape. The fibula is usually shorter and must be lengthened. The reduction is checked by roentgenography in the operating room. If satisfactory a bolt is inserted from the lower end of the fibula to the upper end of the tibia and tightened with 2 nuts on 2 washers (Fig. 1). In cases with a large posteriorly displaced fragment this procedure is only feasible when the fractures are relatively recent. Calcaneal traction is necessary in the repair of these deformities.

Edge osteotomy. The angle of the deformity and the size of the wedge are determined preoperatively. A lateral and medial incision are used. The incisions are carried down to the bone and the periosteum is elevated on the anterior and posterior aspects of the tibia and fibula. A flexible saw blade is placed anteriorly and another blade posteriorly to the bones. The posteriorly located blade is put on a saw and while the anterior blade helps retract the soft tissue the bones are osteotomized. The same procedure but in reverse is followed with the anteriorly located saw blade. The wedge osteotomy is completed. The position is held by two Kirschner wires (Fig. 2).

The distal channel made by the saw through the astragalus is made parallel to the sole and at least 1 cm. distal to its proximal articulating surface. The proximal channel extends through the tibia and its plane is perpendicular to the longitudinal axis of the leg. The wedge comprises almost all of the astragalus pulley the roof of the ankle mortise the external malleolus, and often all of the medial malleolus.

For arthrodesis the anterior approach is used. An 8 cm. long incision is made. The anterior tibial muscle is retracted medially and the extensor digitorum communis and hallucis muscles laterally. The lower end of the tibia and the neck of the astragalus

are exposed by subperiosteal dissection. The joint is opened widely by cutting the deltoid and fibular ligament. Cartilage is removed from the tibia, fibula, and astragalus. A trapezoid shaped bone graft is cut from the tibia with an electric saw. A hole is scooped out on the proximal aspect of the neck of the astragalus, and while the foot is held in position, the graft is slid down into the prepared cavity.

GROVER L. RAME, M.D.

ORTHOPEDICS IN GENERAL

Le Vay A. D.: A Psychosomatic Approach to Orthopedic Surgery. *Lancet* Lond., 1947 1 15

Le Vay goes on record as stating that the requirements of an orthopedic surgeon do not consist in the mere fitting of a bone graft or application of a well fitting cast. He should have at his command a practical modern conception of psychosomatic medicine. In other words, an orthopedic surgeon must treat the mind as well as the body. They are inseparable. The aggravation or the basic emotional instability of patients suffering from an orthopedic disease must be recognized early and dealt with concomitantly.

The many problems confronting a surgeon these post-war days are not entirely physical. They may be in part (1) psychogenic, (2) viscerogenic, (3) personal maladjustments, (4) fear or (5) a combination of the aforementioned factors. It is reported that in many orthopedic diseases, emotion may greatly modify muscular tension, posture, and even osseous structures. Its psychological mechanism is not clearly portrayed, but the author postulates as follows:

1. If a crippled person is unable to make adjustment, he may escape into a fantasy world (children).

2. Illness and invalidism warrants general attention from the family and the patient becomes the focus of attention. Obviously the psychoneurotic, having made these secondary gains, is reluctant to lose them.

3. Analysis reveals further that a tendency toward accidents in industry is attributable to an unconscious, childish, fantastical desire for punishment, hence the inexplicable industrial casualties.

Rehabilitation of a patient may be retarded especially in long term cases when a surgeon fails to win the respect and affection of a patient. A trivial error may ignite a spark in a patient which may produce an unsatisfactory relationship between the surgeon and patient and thus delay healing. A surgeon should scrutinize his own behavior when dealing with troublesome and irritating patients for a response in the same vein is to enhance neurosis.

Clinical evolution of psychosomatic disorder in deformities such as Dupuytren contracture may have their origin in a tenacious grasping person in unconscious muscular activity of the palmaris longus muscle which sets up a chronic tension along the fibers of the palmar fascia and results in hypertrophy and contracture. Similarly, in a patient suffering from visceral neurosis the motility and behavior of the organ affected primarily and this affects the intrinsic

pattern of that organ. In the case of the stomach, an ulcer may appear while in the large bowel, ulcerative colitis may become discernible. A man who is tired of battle develops a paralysis—conversion hysteria.

Emotional states of the mind are alleged to reflect upon the tones of the skeletal and visceral muscles. Psychoneurotic fatigue may be due to prolonged hypertonicity which can be abolished by deliberate relaxation. Fibrositis and myalgias are expressions of local tension in neurotic states. An inner current of emotions may also influence "tennis elbow," hysterical torticollis, spasmodic flat foot and many other abnormalities. The psychological mechanism of "tennis elbow" for instance, is based upon long continued spasm associated with the mental concept of clenching the fist.

Rheumatic symptoms may be symbolic of inner tension manifested by stiffness, fibrositis, and myalgias and may be an expression of resentment against an unfortunate circumstance.

Visceral neurosis is capable of producing preulcerative lesions in the gastrointestinal tract, dysmenorrhea, bronchial spasm, dermatoses, and angina pectoris, as well as bone lesions. Although bone is less labile its blood supply cannot escape the deleterious vasospasm with its resulting functional ischemia and hyperemia, and, finally sclerosis osteoporosis, osteo deck atrophy and even Paget's disease.

SAMUEL L. GOWAN, II, M.D.

Steindler A.: The Newer Pathologic and Physiological Concepts of Anterior Poliomyelitis and Their Clinical Interpretation. *J Bone Surg* 1947 29 59.

The interpretation of the clinical features of infantile paralysis has been greatly enhanced by the newer studies in the fields of pathology and physiology.

Since Charcot's time, pathological studies have led to a gradual extension of our concept of the seat of the disease. This concept now includes many parts of the central nervous system, and it is much more adaptable for an explanation of the clinical symptoms and course. The selectiveness of the paralysis and the prevalence of the partial over the total paralysis of muscles suggest a spotty destruction of neurons with mesodermal glial infiltration and cording. The absence of clinical paralysis is due to the scattered distribution of the motor neuron lesions.

The second point of clinical interest is recognition of the reversibility of the anterior horn lesions. Obviously, complete destruction of the anterior horn cells is final and permanent damage, yet up to a certain point the changes seen in these cells must be reversible, just as the inflammatory glial infiltration and the perivascular lymphocytic exudates or cuff are reversible. The following is essentially the sequence of changes in the motor cells of the horn: the chromatolysis, the sharply outlined acidophilic inclusion of the Nissl bodies, and the peripheral arrangement of these bodies, then the loss of cell outline, complete disintegration and crumbling of the

cell followed by satellitosis of the nucleus phagocytosis and, finally gliosis.

The next clinical symptom to be explained on pathological grounds is the spasm. It is now believed that spasm represents a dysfunction of the interneuronal, or so-called internuncial cell group of the anterior horn. There is no doubt that it is a most frequent symptom and that it is entirely different from contracture. During the 1944 epidemic in Iowa, the author found spasm in practically all cases and almost invariably in the quadriceps.

It is not impossible that the symptom of so-called mental alienation represents the loss of voluntary control, a physiological block within the central nervous system and, more specifically in the system of synapses located all the way from the cortex to the cord. While this is recognized as a transitory and reversible stage, it may appear as a real paralysis. In contrast to the changes due to destruction of the anterior horn cells these changes are entirely reversible and may well explain some of the early and remarkably rapid cures.

Studies in physiopathology have been carried on in recent years with the center of interest on the muscle and the neuromuscular junction.

The histological corollary of regenerative ability of the muscle fibers has been studied. Simple atrophy shows a shrinkage of the fiber and apparently an increase of the sarcolemma nuclei; later there is a disappearance, first of the cross striation and then of the longitudinal striation. It is believed that these stages are still reversible. The more advanced changes in the muscle begin with vacuolation, necrosis, and crumbling of the sarcoplasm, proceed to proliferation of the interstitial tissue, and finally to fibrous or fatty substitution of the parenchyma. These latter changes are believed to be irreversible.

Bouman and Schwartz showed in electromyograms that spasm is a general phenomenon in infantile paralysis appearing in the synergist and antagonist alike, and has nothing to do with denervation

of the motor horn. It finds a plausible explanation in the dysfunction of the internuncial cell group, which has lost its inhibitory effect on the spinal reflex mechanism. Spasm does not exist in the totally flaccid paralyzed muscle.

Moldaver emphasized the electroprognostic value of chronaxial measurement. The muscles with only slightly increased chronaxia have a good prospect of recovery while those with prolonged chronaxia or those not responding at all offer a poor prognosis.

The experiments of Hines and his associates showed that the failure of the muscle to develop effective tension is the cause of atrophy; they also found that inactivity and immobilization retard neuromuscular regeneration while a program of early muscle use promotes it. These authors further found that electric stimulation greatly retarded the loss of weight and the loss of strength of the muscle in the period which preceded its reinnervation. Finally they found that not even the resultant fatigue seemed to have an injurious effect on any phase of neuromuscular regeneration.

While these more recent studies in the pathology and physiopathology of muscle and peripheral nerves may not have brought about anything resembling a complete and radical change in the management of anterior poliomyelitis they have produced important modifications in our concepts of conservative treatment.

The rules pertaining to the application of heat and rest and the avoidance of stretch reflexes in the affected muscles are still being adhered to and in addition, during the period of hyperesthesia, all limbs are kept in proper position. Casts are almost never used and braces are applied only to prevent deformity. Weight bearing is allowed as early as possible and recumbency is prolonged only in patients threatened with spinal asymmetry. Early massage and systematic active and passive movement are especially important. Early mobilization favors neuromuscular regeneration.

RUDOLPH S. REICHER, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Schroeder E.: Case of Spontaneous Rupture of the Subclavian Artery. *Acta chir scand* 1947 95 17

The author notes that arterial ruptures are rare and that they are usually caused by traumatic injury. The so-called spontaneous ruptures as a rule are due to arteriosclerosis or inflammatory changes in the wall of the arteries.

A report is given herewith of a spontaneous rupture of the right subclavian artery in a sixteen year old boy who died 6 hours after admission to the hospital. In giving blood transfusions to him the veins were found to be strikingly fragile. Post mortem examination revealed a large hemorrhage into the soft parts of the right shoulder. The starting point of the hemorrhage was found to be a rupture of the subclavian artery. The connective tissue and vascular tissues in the veins as well as in the arteries were very hypoplastic.

The rupture is attributable to a combination of a mechanical factor and a disposition to abnormal fragility of the vessels. This new finds support in the literature and in the author's experiments.

The treatment of this injury will consist mainly in ligation as usually there will not be time enough for suturing of the vessel. The rupture is approached through a longitudinal incision and if necessary the clavicle may be divided.

Ligation of the subclavian artery is followed by gangrene of the arm in 4.8 per cent of the cases. It is important to remove the extravasated blood so that the collaterals may develop. According to Leriche and others, the subclavian vein should be ligated at the same time.

HERBERT F. TACHTON, M.D.

Albert F.: Problems in Arterial Surgery. *Edinburgh M J* 1946, 53 6 1

The author summarizes in brief his previous work on post traumatic dystrophy wherein he was able to demonstrate that the origin of all post traumatic physio-pathic disturbances was to be found in the vasomotor reflexes evoked by injuries however slight of all articular and mainly periarticular tissues. He observed that these reflexes persisted in spite of proximal section of the nerves of the limb and of section of the nerve roots and sympathetic chain, but that, on the other hand, they disappear after degeneration of the nerves of the limb they were axon reflexes. While these vasomotor reactions persist after section of all nerves at the base of the limb, blockage of the same nerves by novocain at the same level suppresses them entirely; thus, nerve block with a local anesthetic is not really a physio-logical section, but it functionally puts out of use all the affected neurons as if they were momentarily degenerated. An outgrowth of this experimental

study was the preventive or curative treatment by the infiltration of novocain especially in ankle sprains or joint injuries.

Clinically it has been known for a long time that an arterial injury which is followed by local thrombosis or by any irritation of the arterial wall may cause vasomotor reflex disorders in the corresponding limb which sometimes seriously threaten the vitality of the limb. However, resection of the injured fragment of the artery, or blockage of the appropriate sympathetic ganglia may prevent these reactions and save the limb. Similar disorders can be seen in arterial spasm, spontaneous or traumatic, and infiltration of the nerves or ganglia with local anesthetic or sometimes, the interruption of nerve pathways by spinal anesthesia gives rapid improvement. Intra-arterial injection of the anesthetic is particularly useful when the spasm does not entirely obliterate the vessel.

In order to trace the origin of these reactions the author considered it advisable to obtain an accurate appreciation of the vasomotor reactions which follow a simple lesion, such as obliteration of a main vessel. Thus he observed that (1) compression or simple ligation of a main artery regularly causes not vasoconstriction but marked and prolonged vasodilatation in the corresponding limb (2) this dilatation is still more marked if the vessels have been previously constricted and (3) these vasomotor responses to arterial compression or ligation are absolutely independent of the central and peripheral nervous systems. The main cause of the vasomotor reactions is to be found in the physicochemical modifications of the peripheral blood and interstitial fluids, under the influence of a cellular metabolism impaired by arterial obliteration. The author suggests a clinical application of this vasodilatory phenomenon in (1) post traumatic disorders (2) surgical edema of traumatic origin, (3) traumatic osteoporosis, (4) delayed union of fractures and (5) circulatory disturbances following endarteritis. When used for treatment, arterial compression is done with the fingers of the nurse or the patient himself and is applied to the main artery as high as possible. The degree and duration of the vasodilatation are proportional to the duration of the arterial compression (from 5 to 15 minutes) and to the intensity of the previous peripheral vasoconstriction.

A similar study was conducted in investigating the effects of venous compression, and it was found that there is always a rapid rise in the peripheral pressure following such compression but that the rise is nearly always preceded by a slight fall. However rather than that these two phenomena follow each other it was demonstrated that they actually occur together, the vasoconstriction affects the main arterial tree, the large vessels being slightly constricted and the smaller ones sometimes obliterated, while the

very small ones are dilated. The fall of the initial pressure, after venous compression corresponds to the dilatation of the small vessels which persists despite the secondary rise of pressure. The author states that this arterial vasoconstriction subsequent to venous compression is the mode by which peripheral circulation is improved when a main arterial ligation is necessitated and ligation of the companion vein is done. The arterial ligation causes a steadily increasing fall of peripheral blood pressure because of the vasodilatation it brings about the vasoconstriction produced by the venous ligation brings this pressure back to a more normal level. The main indication for ligation of the companion vein is in cases of very large injuries even with combined arterial and venous lesions when other techniques for inducing peripheral vasodilatation become ineffective. These experimental procedures are offered as a possible mode of surgical therapy in diseases of peripheral vascular origin. EDWARD H. CAMP, M.D.

Sette Junior A.: Primary Thrombosis of the Axillary Vein. A Case of Traumatic Origin (Trombose primitiva da veia axilar. Sobre um caso de origem traumática). *Arch. brasil. med.* 1946 36 361

A case of primary thrombosis of the axillary vein of traumatic origin is described by the author. A woman, aged 31, with a severe toxic infectious syndrome of unknown origin fell on her right shoulder while attempting to get out from her bed. A few hours later she showed a picture of a complete obstruction of the right axillary vein due to thrombosis. Twenty cubic centimeters of a 2 per cent novocaine solution were injected into the stellate ganglion and the first three dorsal ganglia via the paravertebral route. A few minutes after the injection the axillary temperature rose from 99.3 to 100.7 and a myosis of the right pupil developed. A respiratory collapse 30 minutes after the injection did not yield to artificial respiration and intracardiac injections of adrenaline, and the patient died 3 days after the accident from circulatory failure.

The autopsy revealed an obstruction of the venous circulation of the right upper extremity while the arteries were normal in appearance. The histologic examination of the involved axillary vein disclosed a partial disintegration of its endothelium beneath a red thrombus. These findings as well as the absence of inflammatory reaction in the venous wall justified the assumption that the trauma played a significant role in the genesis of the venous thrombosis which was facilitated by the coexisting circulatory stasis and the toxic infectious condition of the patient.

JOSEPH E. NARAT, M.D.

BLOOD TRANSFUSION

Snyder H. E.: Replacement of Blood. *J. Am. Med. Ass.*, 1947 133 310.

The author reviews his experiences in the North African and Mediterranean theaters during World

War II, beginning with the early recognition that although plasma is valuable whole blood transfusions are imperative in the severely wounded.

By January 1944, before a blood bank was in operation blood was being used at the rate of 1,474 pints (224 c.c.) per battle casualty admitted to the hospitals. In the latter part of February 1944 the first blood was delivered from the American blood bank to the Fifth Army Units at Anzio Italy. In the period from January to June, 1944, the consumption rose to 0.5 pint (237 c.c.) per battle casualty admitted. In the next 6 months it rose to 0.666 pint (330 c.c.) per battle casualty, and in 5 months of war in 1945 1.02 pints (483 c.c.) per battle casualty admission was used. It is also interesting to note that in this period the percentage of battle casualties receiving blood rose from 24.3 per cent in January 1944 to 40.6 per cent for the year 1945.

This increased use of blood accounted in a great part for the reduction in mortality. At the same time the use of plasma continued to approximate the figure first attained in the Sicilian campaign when 30.2 per cent of battle casualties were administered plasma. The average amount of plasma given per battle casualty admitted to hospitals likewise varied little from 0.5 of one unit (250 c.c.). These figures are for the use of plasma and blood in forward hospital installations. Usually plasma alone was available in aid stations collecting stations and clearing stations.

The use of large quantities of plasma in resuscitation of a patient prior to his admission to a hospital often rendered the problem of preparing the patient for surgical intervention more difficult. It was used in amounts of only enough to render the patient transportable to the hospital where whole blood might be used.

Many laboratory and clinical observations were made and allow the following conclusions:

Lowered blood volume in the shock of battle casualties is due entirely to the loss of whole blood and not to loss of plasma except in those cases in which there is gross peritoneal or pleural contamination beginning sepsis gas gangrene, a burn, or a crush injury.

When whole blood has been lost whole blood is the replacement medium of choice, particularly when the loss has been large. Of course, there may be other factors such as cardiorespiratory embarrassment which must be managed with the same promptness as is reduced blood volume.

Shock may be divided into four broad categories on the basis of etiologic factors: (1) trauma and hemorrhage alone (2) trauma and hemorrhage plus contamination or sepsis (3) trauma and hemorrhage plus cardiorespiratory embarrassment and (4) trauma and hemorrhage plus contamination or sepsis plus cardiorespiratory embarrassment. In an analysis of 523 casualties in which the immediate cause of death was shock on this basis, 182 belonged in the first category, 120 in the second, 147 in the third, 78 in the fourth, and 2 were undetermined.

On admission of a battle casualty or any wounded person, a rapid complete survey of the situation must be made with the immediate application of the indicated resuscitative measures. Primarily this is concerned with blood replacement, and it is recommended that as much as 1,000 c.c. of blood that is not cross matched may be given rapidly if the blood pressure is not obtainable. The first 500 c.c. may be given in as short a time as 5 to 10 minutes. Once a systolic blood pressure of 70 has been obtained the rate of transfusion should be decreased. Oxygen is also indicated. If a systolic blood pressure of 50 to 60 mm. of mercury cannot be obtained by the rapid administration of 1,000 to 1,500 c.c. of blood, immediate surgical intervention may be required. The transfusion must, of course, be continued under these circumstances.

Observations at operation may dictate the type of further replacement therapy. Abdominal wounds, peritonitis and/or gross contamination of the peritoneum with feces without much blood in the peritoneum call for plasma therapy rather than more blood.

It has been desirable to administer 1,000 c.c. more of blood or plasma after systolic blood pressure approximates normal. This rule applies as well in those cases in which the shock is not of such severity. Whenever possible the blood is cross matched. It is emphasized that the supportive therapy of blood or plasma is continued through a cannula while therapeutic, as well as diagnostic procedures are being completed.

Those patients in whom the systolic blood pressure is 90 or more, and whose pulse rate is a little rapid, but who have wounds of such an extent and number as to indicate impending shock, should

be given a transfusion of 1,000 c.c. of blood prior to surgical intervention.

Further transfusion of whole blood is frequently necessary in the postoperative period, during which all observers have noted the appearance of anemia.

Forward hospitals actively engaged in caring for battle casualties are ideally furnished with blood from a base transfusion unit. Banked group O blood titrated for anti A and anti B agglutinins was found most satisfactory. When the agglutinins are in a titer greater than 1 to 64, the bottle is labeled for group O recipients only. Low titer group O blood, or blood in which the anti A and anti B agglutinins are present in a titer less than 1 to 64, is reserved for group A, group B and A B recipients and for use in emergencies without cross matching in amounts up to 1,000 c.c. All blood was drawn into vacuum bottles containing citrate and topped with dextrose solution as a preservative, and used within 7 days.

The transfusion of whole blood was found to be a most essential measure in the management of battle casualties in the general hospitals in the base, prior to and during the time of reparative surgical intervention. Five hundred to 1,000 c.c. of blood were given daily until normal hematocrit readings were obtained.

In 1944 and 1945 68 patients are known to have died in the Fifth Army hospitals of pigment nephropathy or nephrosis of the lower part of the nephron. In 31 other cases nephrosis contributed to death. It was believed that in the vast majority of instances the transfusion of blood was not the underlying factor but that the condition was due to other factors probably depending on a severe degree of shock over a considerable period of time.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Barman, J. M. and Liljestrom, E. Cutaneous Graft from Germinal Epithelium of Follicular Origin (Injerto cutáneo por sembrar de gérmenes epiteliales de origen foliular) *Rev. med. Rosario* 1946 36 67.

The formation and regeneration of the epidermis is a result of the karyokinetic activity of the stratum germinativum which maintains constant reproductive activity. The epidermis lacks blood vessels and lymphatics, nourishing itself with plasma from the vessels of the dermal papilla. Because the follicular pile is formed by an epithelial pocket which covers a dermal depression in the center of the hair, the authors utilized the ends of hair for skin grafting.

If hairs are extracted and the sheaths that cover the ends are deposited over an ulceration, germinal and proliferative units with nutritional elements belonging to them will have been planted. In contrast, grafts of old layers of superficial epidermis may act as foreign bodies for they have no subdermal tissue. A partial necrobiosis results which produces an alteration of the covering epidermis.

Placing of the follicular sheaths over a surface to be grafted is a simple harmless procedure, but efficient in producing normal skin. By planting a sufficient number of germinal units of epithelium, even large areas can be covered rapidly, however it must be borne in mind that only part of them take. Hairs from the same patient or another may be utilized. The skin obtained is elastic and resistant and has been demonstrated histologically to be of a normal constitution. Not only are the areas covered with epithelium, but the formation of scar tissue is prevented. The tissue formed by the follicular sheath becomes skin when planted on a cutaneous surface and has the pect of mucosa when transplanted on mucosa, conjunctiva or glands.

Good results were obtained in 11 patients with the following technique:

With a Pean tweezers a number of hairs are extracted preferably from the periphery of the scalp while with another tweezers the hair is removed and the sheath which is composed of germinal epithelium, is left. This epithelium is deposited on the ulcer and adheres immediately to the base. The ulcer is covered with vaseline gauze or gauze soaked in saline solution and renewed every 24 to 48 hour. In some cases human plasma and topical thrombin was utilized so as to enmesh the germinal epithelium in a retaining film. ARTHUR F. CIRIELLO, M.D.

Homan, J. Venous Thrombosis and Pulmonary Embolism. *England J. M.* 1917 236 196.

In the past decade it has been shown that when autopsies examinations of the legs are thoroughly

made thrombosis is found in the deep veins of the calf in almost 50 per cent of the cases. Much of this thrombosis is terminal and in no sense a cause of death yet it fits in with the clinical experience in calling attention to a process that is observed relatively frequently in the hospitalized patient and one which may readily become a source of embolism.

Thoracic symptoms and signs of pulmonary embolism may be expected in more than 50 per cent of all cases. Pain pleuritic in form and cough combined with hemoptysis are extremely important diagnostically.

Associated symptoms and signs of thrombosis in the legs are elicited with a frequency proportional to the diligence with which they are sought. The subjective complaints are pain accompanied by local deep tenderness particularly on the outer posterior aspect of the lower leg. The objective signs are slight increase (by measurement) of the largest diameter of the calf, an increased firmness or elasticity on compression and a tendency to resist dorsiflexion. Slight cyanosis of the foot may be observed on standing or even on hanging a leg out of bed, and edema on more prolonged dependency.

A recurrence of an increase in the pulse rate and an elevation of the temperature may be observed after these had leveled off following operation or injury. Some degree of circulatory failure may result reflexly from any infarction. The general circulation may react rather violently to the lodgment of an embolus and yet the circulation may readjust itself within a few hours if no further insult occurs.

Röntgen ray evidence of pulmonary infarcts is of importance but films taken in bed usually show poor delineation of the infarct. Not all emboli produce infarction because of the unpredictable efficiency of the collateral pulmonary circulation. Electrocardiography may be pathognomonic soon after an embolus has lodged and is also useful in excluding coronary thrombosis.

The patient under observation for thrombosis should have the calves and ankles carefully measured daily. Instead of being soft and relaxed one calf may feel more firm to the grip of the fingers and be somewhat larger than the opposite one. The muscles may be irritable and deep tenderness may be discernible along the course of one of the major vessels or in the popliteal space. An insufficiently appreciated, but useful proof of deep thrombosis is the presence of a thrombosed area in a superficial vein particularly on the back of the calf. As a rule this thrombosed vein is all the more noticeable because no varicosity is present as an excuse for a local thrombus.

Homan believes that it cannot be too strongly emphasized that the more silent and inidious the deep thrombosis the more dangerous it is and the more apparent the less liable it is to cause embolism.

Basically there is no true distinction between a quiet thrombosis (phlebothrombosis) and thrombophlebitis although the treatment of the two is somewhat different. All thromboses tend to advance in the end toward a femoriliac obstruction.

Among the general run of postoperative patients, one may expect a lower incidence of thrombosis and embolism than is observed in a group that includes cardiac, prostatic, and extremely sick and elderly individuals. The age grouping is the most important since embolism especially the fatal variety begins to be seriously threatening only in late middle and advanced age. In patients committed to bed by operation accident, and serious illness thrombosis may be encountered often, and emboli in the mild or serious form should be expected to occur fairly frequently in the early stage of thrombosis. These considerations form the basis for prophylactic and definitive treatment.

The first aim of prophylactic therapy is the resumption of normal activities if these are interrupted. Early ambulation tends to restore physiologic normality. It is, however, not fully protective because quiet thrombosis may occur without known cause in everyday life even in young persons. Important is the sitting or reclining position in bed while the legs are relaxed should be avoided; the legs must be actively exercised. Elevation of the foot end of the bed favors a return circulation and avoids venous stasis.

Heparin and dicoumarol may be used prophylactically. Heparin acts directly on the blood delaying coagulation. Its effect is noted by the degree to which the clotting time is prolonged. Dicoumarol acts in the liver to prevent prothrombin formation (prolongation of prothrombin time).

Vein interruption (bilateral femoral vein ligation or section) may be employed prophylactically in patients over 50 years of age as part of the preparation for operation for cancer, prostatism, and serious disorders, particularly when several stage operations are contemplated, and in the treatment of fractures of the lower extremities requiring immobilization and prolonged treatment. The femoral veins are interrupted distal to the profunda branch because at this level protection against embolism is secured without noticeable disturbance of the venous return.

Definitive treatment by means of the employment of anticoagulant drugs is favored at present but surgical interruption of the venous tree at various levels has a fascinating definiteness. Those who employ anticoagulant therapy for established venous thrombosis with or without pulmonary embolism believe that it controls further detachment of the thrombus and also prevents thrombosis secondary to the presence of emboli in the pulmonary vessels, and thus favors healing of the pulmonary infarct. Extension of many thrombi into the popliteal and femoral veins is prevented by the preservation of the useful valves of those vessels. Anticoagulants are indicated in the treatment of established thrombosis when the conditions calling for treatment are neither continuing nor recurrent in thrombosis occurring in

active life in early postoperative and postpartum processes and in thrombosis associated with any severe brief illness including coronary infarction. When embolism has already occurred at any stage of thrombosis the anticoagulants may still be used, although surgical interruption is probably to be preferred.

Surgical interruption of the veins, if ideally performed, ends all danger of embolism. Its success depends on early diagnosis and the exact localization of the thrombus. The disadvantage of the operation resides in the production of a sudden venous obstruction at the common femoral bottleneck, especially when many deep veins in the lower leg and thigh already are more or less occluded by thrombosis. The collateral pathways adequate in early local thrombosis are decidedly insufficient. If the femoral vein is ligated distal to the profunda branch, thrombosis may occasionally short circuit the obstruction with a fatal outcome. Another disadvantage is that the operation throws out of function the important valvular system of the femoral vein, and a considerable readjustment of the venous circulation is then required.

In spite of these objections, bilateral interruption of the femoral vein should be performed in all cases when anticoagulants cannot be given with proper controls and operation is a preferred alternative to the use of anticoagulant drugs when thrombosis has advanced into the thigh, especially when embolism has already occurred. The most preferred level of section is proximal to the profunda. Detachable thrombi higher up (common iliac veins) can be sucked out with the aid of a smooth glass tube introduced into the severed common femoral vein. Some surgeons utilize this surgical procedure even when bilateral thrombophlebitis is present.

Interruption of the common iliac veins is used for recurrent or persistent processes believed to be confined to one leg.

Ligation of the vena cava is performed as a last resort in the presence of otherwise uncontrollable embolism, especially when the causal thrombosis is bilateral and/or unlocalizable.

Homans emphasizes that an operative procedure should be utilized only when it is fully understood what the particular operation may be expected to accomplish. With more experience more definite indications for the use of surgical or chemical methods of preventing and treating thrombosis in the veins of the lower extremities will be available.

ROBERT TURELL, M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Fabian A.: Hand Injuries from the Ironing Machine (O poranek rukožehličnim strojem). *Lit* 1947 2 9.

Ten cases of mangle injury have come under the author's attention. Of these 4 were so slight as to require no special treatment and no disability re-

sulted. The remaining 6 were of a more serious character; however, in only 2 was the use of the hand seriously compromised. There were no amputations. Seven photographic reproductions are given in the original article.

The seriousness of these injuries is ascribed to 3 factors: the weight of the upper roller (30 kgm.) its heat (165-180 C.) and finally the desperate attempts of the victim to free his hand by force. In every case the accident could be ascribed to the carelessness or inattention of the injured person or to lack of adequate experience in the manipulation of the heavy machine. There is a rod extending in front of the rollers as a safety device and this rod is also intended as a means of stopping the machine; however it is frequently necessary to smooth out the material about to be put through the mangle and it is during these manipulations that the hand is apt to become entrapped.

As treatment, the author first removes the hanging tatters of burned skin and then applies a dressing of 10 per cent tannin saline putting the hand and forearm up on a splint. When the burned tissues begin to slough away and suppurate, eubasin powder is applied and the saline changed to unguentum oleum jecoris aselli the dressings being changed twice weekly. Treatment with this unguent results in rapid dissolution of the tags of necrotic tissue and vigorous granulation. The necrotic portions of skin and ligament are carefully removed to avoid starting bleeding. Finally during the period of epithelization a change is made to a 5 per cent rivanol saline.

JOHN W. BAKERMAN, M.D.

Cope, O., Langobir, J. L., Moore, F. D., and Webster, R. C., Jr.: *Expedient Care of Full Thickness Burn Wounds by Surgical Excision and Grafting*. *Ann. S. S.* 1947 135.

Full thickness wounds of the skin have always presented a challenge to the surgeon. Invariably in the patient has languished interminably in the hospital before successful closure has been achieved and if the wounds were extensive the patient has suffered from severe malnutrition.

If the challenge is met by prompt surgical excision of the dead tissue and immediate closure of the wound by grafting infection is precluded, scar tissue with disfigurement and disability are minimized, the period of hospitalization is curtailed, manpower economized and the outlook of the patient heartened.

The expeditious treatment of 32 full thickness burn wounds in 38 patients by surgical excision and grafting at the Massachusetts General Hospital, Boston is recounted. Circumscribed burns of full thickness have been excised and closed by grafting within a few hours after injury; the healing is most gratifying. In wounds in which a delay of a few days between injury and excision was introduced infection ensued itself in spite of the administration of systemic chemotherapy and delayed closure was resorted to in half the cases. The results have been surprisingly good. In the patient with full thickness wounds,

homeostasis has been effected and maintained so that areas have been excised and grafted within a few days. The care of the other areas has had to be postponed because of the precariousness of homeostasis and lack of sufficient donor skin for grafting. The longer the delay in closure the greater has been the infection, the less successful the take of the grafts, the uglier and more disabling the scarring.

It is hard to convince any but the plastic surgeon with his experience in excising old scars, that the best base upon which to place a graft is the one freshly exposed, even if edematous, after excision of burn slough.

The problem of full thickness destruction resolves itself with experience in practice.

Chemotherapy is a valuable adjunct in holding in vasive infection in abeyance in those cases in which the excision and grafting must be delayed and in which the organisms are amenable. Its services are probably superfluous in those patients whose wounds are excised and grafted within a few hours after injury.

JOHN J. MALONEY, M.D.

Harvey, E. N., Koer, I. M., Oster, G., and McMullen, J. H.: *Secondary Damage in Wounding Due to Pressure Changes Accompanying the Passage of High Velocity Missiles*. *Surgery* 1947 31: 318.

Primary damage in wounding results from direct crushing of tissue in front of the moving missile and from stretching and tearing in a wide region around the path of the missile. The stretching results from the formation of a large temporary cavity behind the missile which leaves a region of extravasated blood on collapse. The cavity formation is explosive in character and a comparison is drawn between a shot into tissue and an under water explosion.

Secondary damage occurs only if gas is present and results from the effect of pressure changes accompanying the passage of a missile through tissue on the gas. The pressure changes are of three kinds: (1) shock wave pressures that originate when the missile strikes and that move through tissues with the velocity of sound in water; (2) a high pressure region around the moving missile; (3) pressures, both positive and subatmospheric, connected with the behavior of the temporary cavity.

The events which occur during a shot into a tank of water are similar to those in tissue. Hence an analysis has been made of the cause of damage by suspending tissues or organs in salt solution and shooting among them. Blood corpuscles, frog hearts, and intestinal loops were used. Several high speed motion picture frames and spark shadowgrams illustrate these events which are analyzed in detail.

Damage occurs in gas-free organs only if the tissue is severely stretched by movement of the temporary cavity. When gas is present in an organ secondary damage results from expansion of the gas as a result of the subatmospheric cavity pressure. The expanding gas pocket stretches tissue in a manner quite similar to that of the temporary cavity. Fish in water are sensitive to damage from gun fire or detonation because of their swim bladder.

The high pressure of shock waves resulting from the impact of missiles does not appear to cause damage rather it is decreased pressures that are destructive. Such decreased pressures occur when a shock wave is inverted by reflection from an air surface in this case the low pressure shock wave can cause damage. Injury to men in under water blast probably results from the reflected wave.

JOHN E. KIRKPATRICK, M.D.

Rosenfeld L.: Delayed Suture of War Wounds. *Surgery* 1947 21: 200

With the exception of débridement delayed closure of wounds was the operation most frequently performed in military surgery of World War II. Its importance therefore in hastening convalescence and expediting the return of the wounded soldier to duty cannot be overemphasized.

The present report deals with an analysis of 666 wounds occurring in 315 patients in which a delayed closure was performed. The patients were treated in a general hospital in Italy from November 1943 through May 1945. The cases presented include all of the wounds secondarily closed in one general surgical ward in this hospital. In addition to the general surgical type of patient there were also the maxillofacial and plastic cases and a considerable number of chest cases. Very few of the patients in the first two categories required this procedure, the greater portion of the face wounds having been closed in the forward hospitals whereas, in many of the chest cases, delayed closures were required. In addition to the wounds in which delayed closure was accomplished there were numerous wounds in which closure was not feasible and either partial or complete coverage with split skin grafts was required, and such cases are not included in the analysis. The results obtained in this one ward are fairly typical of the results obtained in 15 other surgical wards in this hospital.

The wounds are divided into two groups: those in which primary union was obtained and those in which, following secondary closure, some wound complication resulted. The wounds with complications may be subdivided into the following 5 groups: (1) cellulitis with purulent exudate, (2) cellulitis without purulent exudate, (3) hematomas, (4) severe stitch abscesses, (5) partial or complete wound separation.

The author has been rather stringent in the definition of the last group. He considered any wound in which the wound separation measured 3.0 cm. or greater in length to fall in this class. Of the total number of 666 wounds 96 or 9.9 per cent fell into the group of wounds with complications.

The observed facts substantiate the supposition that following adequate débridement early secondary suture of the debrided wound is a highly satisfactory procedure. The facility with which wounds can be closed at this early date has been mentioned. It is important that, barring complications, the original dressing not be disturbed until the patient is on

the operating table. The importance of immobilization postoperatively cannot be overemphasized and the author believes that bed rest the first week is a definite adjunct.

The factor of primary importance which has been kept constantly in mind is that of early mobilization and restoration of function in order to hasten the return of the patient to useful duty in this theater. No attempt was made to discuss special problems which pertain to wounds in specific localities, such as the face and hands. Needless to say these two sites withstand closure under tension very poorly.

The suture should be small in caliber. Sutures in the face and neck have been removed in from 3 to 5 days and sutures in the hand usually on the fifth day without wound disruption. The most difficult sites of closure were the long shoulder and scapular wounds so frequently and unfortunately longitudinal in direction, often of considerable length, up to 30 to 40 cm. and with considerable loss of substance. Transverse wounds in this locality close much more readily whereas on the extremities except in the vicinity of the joints the longitudinal wound lends itself most readily to closure.

The scars resulting from these closures frequently leave much to be desired. With no fascial closure, and the wounds often sutured under tension the scars frequently broaden and after a period of 6 to 12 months some scars have been seen to be quite wide. Although muscle hernias frequently occur the author has only rarely observed one which was the cause of pain and dysfunction. Doubtless, in the years to come many of these scars will require excision. For the present, however, the method used suffices as a means of securing early closure of the defect with epithelium, early return of function, and rapid rehabilitation of the patient.

JOHN E. KIRKPATRICK, M.D.

Mansfield O. T.: The Excision and Repair of Deep Thermal Necrosis. *Brit J Surg* 1945, 34: 21.

The surgical excision of tissues irreparably damaged by heat has been advocated for a considerable time but the method has several limitations which may have prevented its practice in suitable cases.

In theory the sooner a devitalized area is separated from its host the sooner will surgical repair be practicable and the shorter the stage of toxic absorption from the infected slough. This is generally accepted, but the corollary of this statement is that, whenever possible, excision of the entire area should be carried out before proteolysis occurs, and should be immediately followed by primary repair. In most cases, such repair can be adequately effected by split skin grafts provided these will have a vascular bed for their reception, exposed tendons or cortical bone for example cannot support any thickness of free graft whatsoever, their failure over such areas will result in further infective necrosis.

If primary excision is to be practicable the following conditions must be fulfilled: (1) the area of necrosis must be capable of total excision; (2) the area to

be excised must not be surrounded by an area of partial thickness skin loss and (3) facilities for immediate repair of the area must be available.

The author presents a case in detail, to illustrate this active approach in the treatment of thermal necrosis.

HARRY W. FRIED, M.D.

Jezek, K.: Contribution to the Chemotherapy of Thrombosis of the Cavernous Sinus (Příspěvek k chemoterapii trombózy sinu kavernózního). *Lit. listy* 1947 2: 35.

Pessimistic authorities have in the past regarded any claimed cures of thrombosis of the cavernous sinus as the result of faulty diagnoses rather than of therapeutic efficacy. They believed that the diagnosis could not be definitely established during life and could be verified only at the autopsy table. The author regards both these postulates as too radical. He has hopes for better results with the new therapeutic agents (sulfonamides and penicillin) and believes that a fairly reliable diagnosis of the condition can be established during life.

The diagnosis is fairly well established in the presence of bilateral edema of the lids, conjunctival chemosis, and exophthalmos developing on the basis of a unilateral septic focus of the face. The diagnosis is further confirmed by oculomotor paresis and involvement of the first branch of the trigeminal nerve, although they may be limited to one side only, and accompanied by a septicopyemic picture (blood picture, blood culture, evidence of metastasis to the lungs). The correctness of the diagnosis will be supported by eyeground findings of congested and tortuous veins, various degrees of loss of visual power and evidence of meningeal irritation. When all the findings are limited to one side the process may be limited to the one orbit or it may have reached the cavernous sinus on that side, but it has not yet involved the other side through the inter-cavernous sinuses.

The author reports 2 cases in which the diagnosis of thrombosis was established by the discussed criteria.

One patient was a young man who had cut a furuncle on the lower lip while shaving, and the other a child of 12 years who had had a carious tooth extracted by a dentist. In both instances the process was far advanced when it came under the author's care, and in both large doses of both sulfadiazine and penicillin were started. After about 3 days of such treatment the mental state of the patients began to clear up, their eyesight improved and their entire condition gradually resolved. Altogether the young man received 900,000 units of penicillin intramuscularly and the child 940,000 units intralumbally and intramuscularly. The final result was complete recovery without sequelae of any kind in both instances.

No conclusion is drawn from these 2 cases, however, they are offered with the thought of having them included in future collected series of such cases.

JOHN W. BRENKIN, M.D.

Putaski, E. J., and Sprinz, H.: Streptomycin in Surgical Infections; Laboratory Studies. *Ann. Surg.*, 1947 125: 194.

It is well established that successful clinical results from antibiotic therapy depend on accurate bacteriologic diagnosis and proved susceptibility in vitro of the causal organisms to the chemotherapeutic agent.

Research on the clinical effectiveness of streptomycin in certain types of infections afforded the opportunity of making correlative laboratory studies.

A broth serial dilution method was devised which consisted briefly in determining the lowest concentration of streptomycin which will produce complete inhibition of growth of the organism to be tested. Sixteen to 18 hours were used as the incubation period and controls were established with a staphylococcus aureus of known susceptibility.

The sensitivity test has been adapted to the assay of streptomycin in the blood and urine. These substances were serially diluted in the range of from 1:1 to 1:32. The urine was first diluted with 20 parts of distilled water because of the high concentration usually present.

Two cubic centimeters of a 1:50 dilution of a 6 hour culture of the test organism in broth were added to the tubes containing the serially diluted body fluid being assayed. Results were read after incubation for from 16 to 18 hours. Controls were established using pretreatment urine and blood and diluted them in the same manner.

The absorption of streptomycin after intramuscular injection was observed to reach the maximum concentration within 30 minutes; this lasted about 3 hours. The drug was rapidly excreted in the urine and, after oral administration in the feces, the rate was slower than the reported rate for penicillin. The effective dose seemed to be 0.4 gm. given by the intramuscular route every 4 hours.

Streptomycin was recovered from the bile at autopsy and from T tubes in one-quarter the concentration present in the blood serum.

Pericardial fluid, pleural transudate, and ascitic fluid contain from one-quarter to one-half the concentration in the blood serum. Streptomycin does not diffuse readily from the blood stream into the cerebrospinal fluid.

Traces only reach the prostate and this seems to explain failure in the treatment of chronic lesions of the prostate due to susceptible organisms, even with relatively large doses of streptomycin administered parenterally.

Pus obtained from thick walled abscesses in 4 cases contained no streptomycin. Thus, parenteral administration of streptomycin will neither sterilize nor cause abscesses to disappear. Streptomycin activity is not influenced by pus except mechanically.

The susceptibility of bacteria to streptomycin was tested. The mean blood serum level of 16 microgram per cubic centimeter which is maintained by the intramuscular injection of 0.4 gm. every 4 hours was the basis for the classification of gram-negative bacteria as follows:

Inhibition by 4 mcgm./c.c. streptomycin—very sensitive.

Inhibition by 16 mcgm./c.c. streptomycin—sensitive.

No inhibition by 16 mcgm./c.c. streptomycin—in sensitive

No inhibition by 128 mcgm./c.c. streptomycin—resistant

This classification also applies to infections of the genitourinary tract despite the fact that streptomycin is excreted in high concentration in the urine. Experience showed that bacteria that grew in a concentration of 16 mcgm./c.c. were rarely eradicated from the urine.

The many organisms studied showed a wide variance in susceptibility to streptomycin and showed the need for testing organisms before streptomycin therapy was used.

A comparison of susceptibility of 250 strains of cocci positive to both penicillin and streptomycin was made. In general, organisms resistant to penicillin were susceptible to streptomycin, and vice versa. There may be some value in giving both drugs because subinhibitory amounts of streptomycin and penicillin combined are cumulative in effect.

Dosage principles were derived from these studies.

Doses of 0.5 gm. of streptomycin administered intramuscularly every 4 hours maintained blood serum levels in excess of 16 mcgm./c.c.

There is no evidence that additional benefits accrue from doses in excess of 3 gm. a day administered parenterally regardless of the type and severity of the infection.

The anatomic location of the lesion and the concentration of streptomycin attainable at the site govern the dosage and mode of administration.

Local administration is necessary in the treatment of infections of the ear, meninges, brain, pleura, trachea, and bronchial tree. The dosage employed is from 50 to 250 mcgm. dissolved in an appropriate amount of sterile isotonic saline solution.

Oral administration is required for intrauterine infections. A dosage of 1 gm. every 8 hours in water is optimum.

Drug fastness developed rapidly even in bacteria that were susceptible. This occurred most commonly in the treatment of urinary infections. Once drug fastness occurs, it is irreversible and drug fast bacteria produce drug fast bacteria. The change is specific and does not indicate concomitant resistance to other chemotherapeutic agents.

EDWARD R. DOMAGUE, M.D.

Zint J. H. A. Wyle, M., Nichols, A., and Rhonda, J. E.: The Use of Streptomycin in Surgical Patients. *Surgery* 947 31 175

In the treatment of infections caused by gram-negative bacteria, streptomycin promises much the same therapeutic effectiveness that penicillin has manifested in the treatment of infections caused by the gram-positive organisms. It remains to be demonstrated whether or not this impression gained

from in vitro experiments is confirmed by clinical experience. Although streptomycin is effective in the treatment of certain gram-positive organisms in general its effectiveness against these organisms is not as great as that of penicillin. Data which the authors wish to summarize have been obtained by a group of individuals working on several phases of this problem at the University of Pennsylvania, Philadelphia.

Streptomycin first described by Waksman and associates is obtained from cultures of *Actinomyces griseus*. Thus, 1.0 gm. is equivalent to 1,000,000 units, a moderate daily dose.

Studies of the acute toxicity of streptomycin indicate that it is definitely more toxic than penicillin. Nevertheless the margin of safety between the therapeutic and a definitely toxic dose is wide. Acute toxic symptoms such as palpitation, headache, flushing of the skin, arthralgia, and delayed fever often occur at dosage levels of 4.0 to 5.0 gm. per day when given in divided doses intramuscularly and tend to limit the dosage to less than 4.0 gm. per day. No evidence of toxicity has been noted following oral administration.

Streptomycin is widely distributed in body fluids, except spinal fluid, after parenteral administration, but apparently it does not readily cross the wall of the alimentary tract. Hence, it should be given orally if it is to influence the flora of the feces.

It is effective in many urinary tract infections of both gram-negative and gram-positive organisms that have failed to respond to penicillin and sulfonamides but not in all. It has, perhaps, a special field of usefulness in infections due to *Bacillus proteus* and *Bacillus pyocyaneus*.

It has exerted a beneficial influence on the course of experimental peritonitis in dogs. The difference was statistically significant when combined with an earlier group of experiments in a laboratory. The therapeutic effect, however, was not as great as that with a combination of sulfonamides and penicillin.

Streptomycin appears to be a very effective agent in reducing the bacterial count in the stools. It reduced the coliform organisms to a greater degree than *saccharin*, *salicylic acid*, and reduced the *Streptococcus fecalis* and *clostridia* to a much greater extent.

JOHN E. KIRKPATRICK, M.D.

Kloosner A. R. Treatment of a Case of Noma with Penicillin (Ein mit Penicillin behandelter Fall von Noma der Wangen). *Ann. Chir. Gyn. fenn.* 946, 35 5

Following the extraction of a tooth, a case of noma occurred in a 17 year old girl. On transfer to the surgical department, this undernourished patient was found to have a severe secondary anemia. This condition was accompanied by a necrotic, foul smelling ulcer (about 4 by 5 cm.) involving the left cheek. The lesion was sharply demarcated from the normal buccal tissue by an edematous, parolled appearing border. Irritation of this lesion elicited no bleeding.

Treatment consisted, first, of the application of neosalvarsan and sulfathiazole powder for 3 days, without healing. After this penicillin was administered in doses of 10,000 units every 4 hours until a total of 270,000 units had been given. Within 24 hours after the penicillin was first given, healing was apparent and the foul odor had decreased. The patient was discharged from the hospital approximately 18 days later with a healed fistula in the cheek through which the teeth were visible. Three months later the patient was seen again and at that time there was a healed scar at the site of the previous perforation.

The discussion of this case includes a complete historical review plus a résumé of the important contributions to the literature on this subject.

SAMUEL J. FOOTLICKSON, M.D.

ANESTHESIA

Mazzola, V. P.: Sodium Pentothal Anesthesia in Major Obstetric and Gynecologic Surgery. *Am J Obst* 1947 53 207

The use of intravenous sodium pentothal anesthesia in 300 consecutive major obstetric and gynecologic cases is reported. There were 50 obstetric cases consisting of 45 cesarean sections and 5 cesarean sections with supracervical hysterectomy. The gynecologic cases were divided between major vaginal and abdominal procedures. The continuous method of intravenous administration of sodium pentothal is advocated, with 2 per cent, 1 per cent and 0.5 per cent solutions. A dose of less than 1.5 gm. of sodium pentothal was used in this series. No maternal or fetal deaths and no postoperative complications were encountered.

Sodium pentothal intravenous anesthesia can be used with success in major obstetric and gynecologic surgery. It is a safe anesthetic for its dangers are minimal in the hands of a competent properly trained anesthetist. In cesarean sections the precaution should be taken that the baby is delivered within 5 minutes of the injection. This anesthetic is of advantage because the injection is pleasant and simple and the induction is rapid and easy in that the patient falls asleep and quietly passes into the stage of surgical anesthesia. Dosage is easily controlled. Recovery is rapid and without vomiting or distention. It is excellent for debilitated and aged patients.

It is contraindicated in advanced cardiac disease with dyspnea, toxemia, and obstruction of the airways. Sodium pentothal does not give good relaxation for extensive abdominal procedures, but it can be supplemented by other methods.

JOHN R. WOLFF, M.D.

Ericsson, N. O.: The Frequency of Complications, Especially those of Long Duration after Spinal Anesthesia. *Acta chir scand* 1947 95 167

Spinal anesthesia appears in an increasing degree to fulfill the needs of a satisfactory form of anesthesia

that has few or no contraindications. The author has studied the existing literature and has examined the records of 784 cases in which spinal anesthesia was used, to acquaint himself with the risks and postanesthetic complications in this connection. The substances used were perocaine (1 to 1,500) and novocain in 5 per cent solution. In only 1 patient in the author's series (with hematomyelia which resulted in death) did anesthesia appear to be the deciding factor.

Nervous symptoms from the anesthetized zone were in the form of paresthesia in 9 per cent of the cases in the author's series, and the longest duration of symptoms was 6 months. No marked cauda equina syndrome occurred. Paresis of the bladder occurred in 17 per cent of the cases with a maximum duration of 10 days. The possible etiology of these nervous symptoms was that of a toxic injury caused by the anesthetic substance.

Nervous symptoms outside the anesthetized zone occurred more frequently than those inside the anesthetized zone, and included such symptoms as diplopia (in 3.3 per cent of the series) and paresis of the upper extremities (in 2.5 per cent of the series) which in 0.9 per cent persisted for more than a year.

Headache is unquestionably the most common sequela and is said to occur in from 10 to 25 per cent of cases. It can last as long as a year and the author states that it has occurred in from 12 to 25 per cent of cases following ordinary lumbar puncture. In his series headache was of short duration in from 10 to 13 per cent of the patients, in from 5 to 9 per cent of patients the headache was of more than 1 week's duration and in 0.3 per cent, headache was present for over 1 year. It is assumed to be due to spinal fluid hypotension which arises through a leakage of spinal fluid, caused by disproportion between the arterial and spinal fluid pressure, and bringing with it an increased stretching of the arterial walls of the cranium. A nervous constitution with predisposition to headache is considered to be responsible for headache of long duration. Ergotamine tartrate is suggested as a therapeutic measure.

Nausea and vomiting, though less common after spinal than after inhalation anesthesia, were possibly of somewhat longer duration. Vertigo was of short duration and relatively insignificant. Backaches occurred in from 3 to 22 per cent of cases in the literature and in 3 per cent of the patients in the author's series most often after gall bladder operations due possibly to overstretching of the spinal muscles. The fall in blood pressure during spinal anesthesia had no relation to the late symptoms. Repeated spinal anesthesia at short intervals did not increase the risk or frequency of postoperative complications.

Sixty nine per cent of patients were entirely free from discomfort after perocaine anesthesia, 21 per cent had slight discomfort, and 10 per cent had severe discomfort. After novocain anesthesia the figures were 80, 15 and 5 per cent respectively. The patients who were given perocaine had undergone a

greater number of major operations and it was believed that there was no significant difference in toxicity between the percaline and novocain. The quantity of anesthetic substance used played no role in the causation of the discomforts.

Examination of the 784 cases was accomplished by means of a carefully specified questionnaire which was sent out during the period between 1942 and 1944. It was based on the answers which were received in 784 of 1,206 cases. These answers together with the case returns and anesthetic records have served as the basis of the investigation. The post-operative complications have in practically every case been subjective. Personal examination has shown the complications in some cases to be due to other than anesthetic causes.

The opinion as to contraindications has been revised during the past few years. In the case of cardiac defects, arterial hypertension, or a poor general condition in patients who, as a result of their illness, are poor risks, spinal anesthesia should, in the majority of cases, be the most lenient form of anesthesia, especially in major abdominal operations. Shock presumably should be a contraindication for spinal anesthesia. During pregnancy sensitivity to spinal anesthesia should be an indication for certain restraint and increased cautiousness. Patients with a history of earlier neurological disturbances present certain risks if spinal anesthesia is to be used, and each case of this type should be individualized. Spinal anesthesia has gained an increasingly wide field and should be the ideal form of anesthesia in many operations such as ileus, peritonitis, icterus, and uremia.

The disadvantages of spinal anesthesia are discussed—particularly the occurrence of certain late symptoms must be counted as a definite disadvantage—but compared to the advantages, these drawbacks are believed to be small. It is pointed out that other forms of anesthesia also occasion late discomforts, although these have not been observed and discussed to the same degree. MARY KARP, M.D.

Voylatsko, G.A.: Pseudomonas Pyocyanea Meningitis after Spinal Anesthesia. *Brit M J* 947 79

Reports are presented of 4 cases of Pseudomonas pyocyanea meningitis, 3 of which were of the melanogenic variety. Three of these received intensive sulfonamide treatment by mouth. The fourth had a rapidly fatal issue, and was erroneously given penicillin and only medium doses of a sulfonamide. One of the patients with true Pseudomonas pyocyanea meningitis survived after intensive sulfathiazole treatment 740 gm in 92 days. Pyocyanea meningitis is considered very rare and possibly always of traumatic origin. The patients in the 4 cases recorded had had spinal anesthesia under scurocaine. An aseptic technique is considered important in the prevention of this condition.

The meningitis that occurs is very resistant to treatment early and intensified sulfonamide therapy

is suggested and should be maintained because of the frequency of relapses. Of the 4 cases reported 3 terminated fatally after operation while the fourth case was cured.

MARY KARP, M.D.

Richards, R. K.: Effects of Vitamin C Deficiency and Starvation upon the Toxicity of Procaine. *Current Res Anesth.* 947 26 2.

It was found that vitamin C depleted guinea pigs developed a markedly increased sensitivity to pentobarbital indicated by a prolonged sleeping time. This drug is subjected to destruction predominantly by the liver. Fatty changes in the liver which occurred in these animals were not responsible for the impaired ability of this organ to destroy nembutal, but vitamin C itself was probably involved in the process.

Among other drugs, which are largely metabolized by the liver are most of the local anesthetics. Hepatic damage is known to retard greatly the destruction of procaine. It was considered desirable to investigate the effect of this nutritional deficiency upon the toxicity of procaine.

It was observed that variations in the diet which impaired the vitamin C supply greatly influenced the sensitivity of guinea pigs to procaine. If 300 mgm/kgm were given as little as 15 minutes prior to the procaine, restoration of normal sensitivity followed in animals depleted for 15 to 21 days. It was shown that the greater sensitivity of these animals was due neither to the lowering of glycogen stores in the liver which usually occurs in vitamin C deficiency, nor to the frequently increased fat content in this organ.

A comparison of the incidence of convulsions in starved animals with that of guinea pigs on a vitamin C free diet shows a similar increase of sensitivity for the two groups. Dextrose in liberal amounts restored normal sensitivity ascorbic acid was likewise effective.

Even moderate changes in the supply of vitamin C affect the tolerance to procaine, and general starvation equally lowers resistance. Evidence is given for the possibility of increasing the tolerance to this drug by giving an extra supply of dextrose and vitamin C to animals in the so-called normal nutritional state.

The results of the experiments suggest that liberal administration of dextrose and vitamin C prior to the use of large doses of procaine may increase the resistance against toxic side effects of this drug, particularly in patients in a poor nutritional condition.

MARY FRANCES FOR, M.D.

Crossman, L. W., and Allen, F. M.: Surgical Refrigeration. *J Am M Ass* 947 35 377

A dead limb which for some reason cannot be amputated at once can be preserved by refrigeration to prevent a rapidly fatal intoxication. Interesting case reports representing such situations are presented. One of the patients refused surgery but was kept without pain or toxic symptoms for 6 weeks,

after which time she died of her original cardiac ailment. Another patient, who was chronically undernourished, had a bilateral femoral thrombosis when admitted with but little chance of survival. After 10 days of refrigeration of both legs to the groins, her general condition had improved sufficiently to tolerate surgery safely.

A bad general state of the patient is the usual reason for wishing to delay surgery, but also there is the hope that a lower level of amputation will be possible. With refrigeration anesthesia no tourniquet is needed except briefly at the final amputation. Limbs may be packed in ice while waiting for the legal permission for the necessary amputation. This allows a safe postponement of the operation for several days and at the same time decreases the operative risk.

A still better result occurs when the refrigeration not merely tides over an emergency but prevents amputation altogether. An accident case is cited in which only minimal instead of the usual extensive débridement of badly injured extremities was necessary after refrigeration for 2½ weeks. Refrigeration permits saving the whole of the living tissue, which may be partly sacrificed by the usual débridement.

Reference is made to a previous report which showed that refrigeration aids in restoring fingers which have been cut off so as to hang by a mere

thread of skin. A patient can pack an injured finger in ice and so keep it viable for several hours, should such a time interval be necessary before he can reach a doctor. After the finger is sutured in place the reduced temperature is still continued for several days but it is raised slightly day by day as the nutrition of the severed part returns.

Mention is made of the experimental work of Blakemore and his coworkers in which amputated legs of dogs were kept refrigerated for 24 hours and then replaced with successful healing. If a limb is fairly cleanly amputated in an accident, there is a challenge to any physician to pack such a part in ice and send it along with the patient to a hospital equipped for the necessary anastomosis.

Refrigeration permits application of a tourniquet for much longer periods and with much less harm than when it is not used. In 1 instance a tourniquet was left in place for 27 hours on a refrigerated limb. There was no detectable change either in the zone of the 27 hour pressure or proximal or distal to it.

Cold has the unique ability to inhibit simultaneously pain, shock, infection, toxic absorption, and tissue devitalization. Experiments show that body temperatures of 80° F. or lower are not so effective as the near freezing temperature, however, their inhibition of shock is nevertheless striking.

EDITH EASON, M.D.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

De Castro J M: Fundamental Principles in the Application of Cineroentgenography as an Auxiliary Method to Roentgen Diagnosis. *Am J Roentg* 1947 57 103

The author states that cineroentgenography has been made adaptable to daily use. A 35 mm film is now being used and is superior to a 16 mm film. Practical reasons for the use of cineroentgenography are: (1) a sharp roentgenogram serves as a document of the fluorescent screen; (2) a more careful study of the projections may be made at the leisure of the roentgenologist and other doctors; (3) objective and mathematical studies may be made as a result of tracings. The last method has been termed 'roentgenological chronocinematography' which is a roentgen documentation of the movement of an organ in relation to time.

Cineroentgenography especially in group studies will undoubtedly aid in establishing diagnoses which could not have been made by ordinary roentgen means.

Excellent reproductions are shown of studies of the passage of barium in the gastrointestinal tract; the heart; the mechanics of movement in a patient with congenital pseudarthrosis of the tibia and fibula; and the mechanics of the normal movements of a hand.

MACCRACK D SACRE, M D

Teplick J G., and Drake E H: The Roentgen and Cardiac Manifestations of Funnel Chest. *Am J Roentg* 1946, 56 7

Funnel chest or pectus excavatum, has received only scant attention in the medical literature although it is not a rare condition. The majority of the cases exhibit no symptoms.

The authors report 9 cases of funnel chest which were studied roentgenographically. Several of the patients complained of palpitation and dyspnea especially following exercise but they had not had a serious cardiac embarrassment.

Funnel chest is a developmental anomaly. In 4 of the authors' cases it was of a hereditary nature having occurred in one or more members of the patient's immediate family. In another case it was the result of severe trauma to the sternum which produced an angulated fracture.

The most characteristic roentgen finding is a displacement of the heart to the left with some elevation of the left border from the diaphragm. Since normally the right border of the heart is hidden by the vertebral column, this left shift of the heart is easily interpreted as a true enlargement of the heart, such as is observed in a congenital, or mitral heart. For the same reason the right hilar and trunk shadows which usually are overlapped by the right cardiac border will appear quite prominent giving the im-

pression of pneumonia or congestion. In the lateral view the sternum protrudes backward, lying well behind the chest wall.

Minor electrographic abnormalities are also described in the literature. These occur chiefly in chest leads and are interpreted as being due to a combination of the left shift and axial rotation of the heart rather than to associated myocardial damage. In the authors' series right axis deviation was noted only twice and notching in leads 2 and 3 was seen once. Lead CF was taken in each patient and slight T wave changes in this lead were found to be the most constant variation. In one case there was a bigeminal rhythm due to regularly recurring right ventricular extrasystoles. The authors considered this to be due to irritation of the right ventricle by the constant pressure of the deformed sternum.

The roentgenograms made in the posteroanterior and lateral views, are reproduced in all 9 cases, and accompanied with a brief synopsis of the case reports. The knowledge of this condition is important when interpreting phot fluorograms.

T LUCIFRA, M.D.

Gould C. L., and Dalley M E: Simultaneous Radiographic and Gastroscopic Examination of the Stomach. *Rad diag* 1947 45 8

Simultaneous fluoroscopic and gastroscopic examination of the stomach was made in 4 patients. After various contrast media had been tried in an attempt to find a transparent yet radiopaque substance, the authors finally selected for their studies a mixture composed of equal parts of saturated aqueous solution of methyl cellulose and diiodrast. Immediately after emptying the stomach, 60 c.c. of the mixture were instilled and the gastroscope was promptly inserted while the patient was lying on his left side on the radiographic table the head being supported by an assistant. A preliminary test for the three blind areas encountered at gastroscopy was made on the stomach of a fresh cadaver.

Roentgenograms showed that over inflation with air caused the lower pole of the stomach to move ventrally and to rise (with the patient in the conventional lateral left decubitus position) and interfered with visualization of the pylorus. On the other hand it was found that the blind area in the gastric fundus could be reduced by this method.

The principal causes of blind areas are: adherence of the gastric wall to the front lens of the gastroscope (required focal distance 0.5 cm.), absence of retrograde vision necessary for viewing the dome of the gastric fundus, and separation of the light source from the objective of the instrument causing poor collimation of the field of vision and the field of illumination.

The new omnangle gastroscope, by allowing the angulation of the objective to be shifted at will

during so examination has somewhat reduced the extent of the areas hidden behind the angulus and near the cardia.

A correlation of the roentgenological and the gastroscopic mucosal pattern of the stomach was impossible because of inadequacy of contrast material which tended to pool in the dependent portion of the stomach.

The authors conclude that studies of this nature may lead to an earlier recognition of gastric fixation, especially if it is caused by perigastric disease.

CERHART S. SCHWARTZ, M.D.

Jansson G. Roentgen Diagnosis of Adrenal Tumors. *Acta rad. Stockholm* 1946 27 536

The author reports a case of teratoma of the adrenal in a woman of 51 who was losing weight and had noted a mass in the left side of the abdomen. On examination, a ballotable mass about the size of a fist was palpable just below the ribs on the left. The patient showed no signs of virilism; the blood pressure was normal and urological examination revealed no abnormality.

Roentgen examination showed a mass situated on the medial and posterior aspects of the left kidney, extending from just below the level of the superior renal tip down to within 3 cm. of the iliac crest and producing a concave impression on the psoas muscle. The striking thing about this mass was the dense homogeneous calcification of its upper pole. A pyelogram revealed no intrinsic abnormality of the renal pelvis and calyces, which in spite of the obscuring calcification could be satisfactorily identified by the combined use of upine and lateral views. There was a slight dislocation of the kidney and proximal ureter medially and inferiorly together with rotation of the organ. The upper pole of the tumor lay at about the level of the superior calyces—lower than the normal position for the adrenal gland. It was believed that the mass was either an adrenal tumor or less likely a renal tumor arising in the lower pole of the renal cortex and not affecting the pyelogram.

At operation a neoplasm about the size of two fists was found and easily peeled off the uninvolved kidney. On section it proved to be a partially calcified adrenal teratoma with sarcomatous change of the lower pole, which finding was believed to account for its recent rapid increase in size. It was thought that the rather low position of the upper pole of the tumor as compared with the usual site of the adrenal gland could be explained by the considerable weight of the neoplasm dragging it downward along the dorsal surface of the kidney.

The author who has reviewed a considerable material has never encountered so dense and homogeneous calcification in a renal tumor but considers the finding significant in differential diagnosis as favoring a renal origin. In contrast to such calcification with the quite different granulated plotchylenities often associated with tuberculosis of the region. He refers to 3 other cases of partially calcified

adrenal tumor culled from the literature: one of them a pyramoma showing calcified plaques; he does not discuss the frequency with which calcification or ossification is found in teratomas in general.

LILLIAN DONALDSON, M.D.

Gillespie H. W. Further Observations on the Roentgenological Diagnosis of Lumbar Intervertebral Disc Lesions. *Brit. J. Radiol.* 1947 20 37

The two principal findings in straight roentgenological examination of lumbar disc lesions are decreased intervertebral space and hypertrophic fringe formation. The author believes that up to 45 per cent of all cases of prolapsed disc will show narrowing of the interspace.

One hundred cases showing this roentgen sign are presented. All of the patients complained of backache with or without an accompanying sciatica. Cases showing a decreased interspace attributable to tuberculous or staphylococcal infection or generalized osteoarthritis spondylolysis or spondylolisthesis were not included in this series. Eleven per cent of the patients showed hypertrophic fringe formation at the site of narrowing; 73 per cent of all cases were proved at operation; 10 per cent of the patients (showing only slight narrowing and no fringe formation) had no protrusion. In 26 per cent no operation was performed.

This series of cases was analyzed with regard to the interval between the onset of pain and the demonstration of narrowing of the interspace.

The longest interval was 27 years; the shortest 1 month. In 16 cases there was a time interval of only 1 to 5 months. Seventy per cent of the patients were able to give not only the time of onset of pain but also a definite cause; 25 per cent gave no history of injury but remembered a sudden onset of pain; and only 5 per cent were unable to give either the approximate date of onset of pain or a definite cause of the condition.

R. B. LEWIS, M.D.

Gemignani V.: The Stratigraphic Roentgenological Picture of the Arch of the Large Azygos Vein. (*Il quadro radiologico stratigrafico dell'arco della vena grande azygos*) *Radiol. med.*, Milano 1946 32 342

In 15 per cent of the usual roentgenograms of the thorax the large azygos vein can be seen as a shadow surrounded by air and aerated tissue, i.e., medially by the right bronchus and laterally by the pulmonary parenchyma. Because of its round shape and location the shadow was described by Crane in 1918 as that of a lymph gland, but Bu 1 and Ottonello interpreted it as the arch of the azygos vein where it rides the right bronchus. Absence of this shadow is due to anatomical anomalies of the vein itself. The study of the azygos vein requires three projections: the sagittal, the right anterior oblique at an angle of 45 degrees or more, and the left anterior oblique with only a few degrees of rotation. Because of its communication with the superior vena cava, the right

heart the inferior vena cava, and the portal system by way of the esophageal veins, the azygos vein assumes the role of manometer of the venous endo-thoracic pressure having been found larger than normal in cardiacs in the stage of decompensation in portal stasis, in Basedow's disease and in therapeutic pneumothorax of the left side and smaller than normal in left pleural effusion and in therapeutic pneumothorax of the right side. The method of study consisted in removing from the cadaver most of the vertebral column. This exposed the azygos vein in its straight course to the fifth thoracic vertebra where it curved laterally to ride the right bronchus and enter the superior vena cava. The vein was ligated at the straight end and an aqueous solution of barium sulfate was injected at the beginning of the curve.

In the stratigraphic study after a routine anteroposterior roentgenogram of the chest, a roentgenogram is taken at a stratum at one-half the depth of the anteroposterior diameter and a second one at one half the depth plus 1 cm. If the vein still is not visible a third roentgenogram is taken at a stratum at one-half the diameter plus 2 cm. The other data were as follows: angle of rotation, 15; exposure 0.2 second and focal distance, 150. With this technique, the author was able to demonstrate the shadow of the arch of the azygos vein in 4 patients with chronic myocarditis and beginning decompensation in 1 with moderate pleural effusion in 2 with hepatic cirrhosis and ascites and in 2 with tubercular peritonitis with effusion. JOURNAL OF A. PAPA, M.D.

Mustakallio, S. The Relation of the Microscopic Structure of Laryngeal Cancer to Radiocurability. *Acta radiol. Stockh.* 946: 1-473.

Of 201 cases of laryngeal cancer in which treatment by irradiation was carried out at the Central Institute for Radiotherapy at Helsinki, the author found 67 cases suitable for a study dealing with the relation of microscopic structure to radiocurability. His criteria for the selection of this group were as follows:

The tumor had been studied microscopically in each case; the treatment (referred to in a previous paper in 1944) had not been interrupted in any way; all patients had lived and had been followed for at least 5 years, or had died before then of recurrence. All cases in which the patient had died from some other illness within the 5 year period, but had been free of symptoms of recurrence, were excluded, as recurrence might have occurred before the lapse of the full period of 5 years.

The classification of Broders was followed in grading these squamous cell epitheliomas: grade I with a differentiation of 75 to 100 per cent of cells; grade II with a differentiation of 50 to 75 per cent; grade III 25 to 50 per cent, and grade IV from practically none to 25 per cent differentiation, grade I and grade IV being the easiest to classify. Every effort was expended to make the grading objective. The author stresses not only the difficulty of grading a

given histologic section accurately but also the possibility that the biopsy may not represent the grade of differentiation in some other part of the tumor.

The result of this classification in comparing cell differentiation with the clinical result of irradiation treatment, is presented in the accompanying table. This table shows that the best results were obtained in grade I and grade IV neoplasms—the most and the least differentiated—considered. In general, the least and the most radiosensitive, while the poorest results were obtained in grade III neoplasms. In this connection the author recalls the material of Phillips comprising 71 irradiated neoplasms of the oral cavity in which no correlation could be established between grade of primary growth and its reaction to irradiation. Although, according to Broders, the grade of malignancy of carcinomas is as a rule in direct proportion to their proliferative metastasizing and death-dealing capacities.

In an effort to discover reasons for these results, the author further classifies his material into clinical stages at the time treatment was undertaken, stage I being that in which the carcinoma only superficially infiltrated one or both cords so that the cords still moved freely; stage II being that in which infiltration had extended so deeply into surrounding tissue that the cords were immobile or nearly so or in which extension to cartilage had occurred, and stage III that in which the neoplasm had extended beyond the larynx or had involved lymph nodes.

When the preceding clinical stage was then compared with the microscopic grade, it was found that grade I cases had been treated at a considerable earlier stage of development than the cases of other groups, probably because grade I carcinomas develop relatively slowly and the author concludes that the relatively early stage at which treatment was begun in these cases made up for their relative radio-insensitivity. As regards the relatively advanced clinical stage at which most of the patients in grade IV presented themselves for treatment, he believes their great radiosensitivity to be the compensatory factor which allowed relatively good results to be obtained. For the failure of treatment in grade III cases, he can only suggest that they have the dangerous qualities of both the differentiated and undifferentiated carcinomas—a 25 to 50 per cent of differentiated cells which are radioresistant, combined with considerable tendency to grow rapidly and to metastasize. LILIAN DONALDSON, M.D.

Lehmann P: Treatment of Multiple Bone Metastases with Widespread Osteolysis of the Vertebrae or Ribs by Radiotherapy in Massive Doses Combined with Total Teleradiotherapy. Disappearance of the Radiological and Clinical Signs (Traitement des métastases osseuses multiples avec ostéolyses étendues vertébrales ou costales par la radiothérapie à doses massives associée à la téléradiothérapie totale. Disparition des signes radiologiques et cliniques) *Mém Acad chir. Par.*, 1946 72 571

In no form of cancer are early bone metastases so frequent as in breast carcinoma. Until recently these metastases seemed to be beyond all therapy, and the physician was helpless against the rapid development of cachexia complicated by paraplegias and pathological fractures. Radiation therapy was tried early in these conditions but only lately has apparatus of sufficient potency and effective technique been devised which permit successful check of the metastases. Although it is not yet possible to cure the patient permanently by this treatment life can be prolonged and activity maintained for years. In addition to this, the excruciating pains caused by pressure of bone metastases on nerves are relieved after a short period of treatment.

The author presents 4 cases which were treated by roentgen therapy of the metastases in combination with general teleradiotherapy. The applied doses were about 3 times as high as the usual ones. In order to avoid roentgen damage of the skin and tissues, the author used a method of desensitization which is not described in this article. It is of particular interest that no anemia developed during the treatment on the contrary the erythrocyte count and the hemoglobin increased during the irradiation and only transient leucopenia was observed. On the basis of 50 cases of irradiation of cancer the author believes that the anemia of the carcinomatous patient is due to the progress of the cancer rather than to the irradiation.

The success of the treatment is decidedly impressive. One patient whose history is given in detail complained, 33 months after removal of a carcinomatous breast, of excruciating pains in the left arm, paresthesias in the area of the mandibular nerve, and severe pains in the left lumbar region. The roentgenogram revealed that the entire left first rib as well as the anterior arc of the second were inviable, and another large metastasis was present at the fourth lumbar vertebra, with extensive decalcification so that the superior border of the bone was effaced. Within 3½ months the patient received 51 treatments of total teleradiotherapy and at the same time 23 500 roentgens on the metastases from different fields. Soon after the completion of this treatment the pain in the lumbar region cleared up completely and during the next few months the general condition improved and the pains caused by involvement of the brachial plexus decreased steadily so that about 6 months after the last irradiation the patient was free from all symptoms and had resumed her normal activities. At this time, the

roentgenogram showed recalcification of the first and second ribs and a perfectly normal picture of the fourth lumbar vertebra. Four months later the patient returned complaining of pains in the back. X-rays revealed new metastases in the twelfth dorsal and the first lumbar vertebrae. These were treated by combined teleradiotherapy and focal irradiation with perfect clinical and roentgenological success. Shortly after new lesions appeared at the sacroiliac junction and the right femur which were subjected to the same treatment. At the time of the publication, the patient appeared to be in perfect health. Altogether she had received 55 000 roentgens locally and 78 treatments of total teleradiotherapy. No untoward side effects of the treatment were observed.

WERNER M. SOLMITS, M D

Stampfl W P and Kerr H D: Fractures of the Femoral Neck following Pelvic Irradiation. *Am J Roentg* 1947 57 71

Postirradiation fractures of the femoral neck were first reported in 1927. Since then many additional cases have been reported in the literature. Theories such as necrosis secondary to vascular damage, the use of pelvic fields in irradiation, and bone which fractures easily following irradiation are offered as a cause of these fractures. The most plausible theory advanced is that of vascular damage and bone absorption. Failla showed that bone absorbs 40 per cent more irradiation than does soft tissue. Osteoblasts are supposedly more sensitive than osteoclasts. Boyd stated that the two chief factors in bone absorption are vascular absorption and osteoclastic activity.

Three cases of the present series were studied by means of biopsy. Osteoporosis was the outstanding feature.

Of 1,372 patients irradiated for pelvic carcinoma 12 developed fracture of the femoral neck. This represents an incidence of 0.87 per cent. Lateral fields were used in all instances. The average age was 56 years. Four patients showed additional roentgen changes in the pelvis.

The interval between therapy and the appearance of the first symptoms was 2 years and positive roentgen findings were noted at 29 months. The symptoms were dull pain, becoming progressively worse and aching, especially when the patients were erect.

Roentgenograms made at the time of therapy revealed that the femoral neck was not always covered in the anterior and posterior fields. The roentgen appearance was one of subcapitate mottling (An early fracture line is never absolutely clear.)

Treatment depends on the condition of the patient. In most instances immobilization suffices; in 2 cases with displacement, reduction and immobilization were satisfactory.

The authors are of the opinion that the risk of skeletal damage has been exaggerated. When a fracture occurs, the prognosis is good.

MAURICE D. SACHS, M D

heart, the inferior vena cava, and the portal system by way of the esophageal veins the azygos vein assumes the role of manometer of the venous endo-thoracic pressure, having been found larger than normal in cardiacs in the stage of decompensation in portal stasis, in Basedow's disease and in therapeutic pneumothorax of the left side, and smaller than normal in left pleural effusion, and in therapeutic pneumothorax of the right side. The authors are of the opinion that the risk of skeletal damage has been exaggerated. When a fracture occurs, the prognosis is good.

MAURICE D. SACHS, M.D.

extremity in addition there was hypertrophy of the involved arm, especially of the right hand. The distance from the acromion to the styloid process of the radius was 90 cm. on the right side and 86 on the left. Also the diameters of the right arm, forearm, wrist, and metacarpal region were larger on the right side than on the left. Roentgenograms showed that not only the soft tissues but also the osseous structures were hypertrophic. The cervical spine was intact.

If a flat nevus coexists with hypertrophy of the involved extremity, the condition is called "Parkes-Weber syndrome" while the name Klippel-Trenaunay syndrome is used when the angioma is associated with congenital varicosities and malformations of the face or one or more extremities.

As to the pathogenesis of the condition, variations of the genotypes subject to the mendelian law do not come into consideration. A local congenital malformation is the basis of the condition. Such a malformation may be explained by two theories: the first incriminates anomalies of the arteriovenous net work, while the second considers the syndrome as the result of a congenital sympathetic lesion.

According to the first theory, vascular dystrophy is the primary lesion. Venous hypertension and an excessive blood supply produce hypertrophy of the affected limb. Abnormal arterial distribution and sometimes an arteriovenous short circuit have been demonstrated by arteriography. Surgical intervention, by diminishing the vascular malformation, permits marked decrease in the size of the angioma and of the affected extremity.

However the second theory explains the genesis of the condition in a better way. A functional paralysis of the sympathetic system was very evident in the authors' patient, in whom an acceleration of the blood flow and a diminution of the venous pressure in the involved extremity could be demonstrated. Apparently the sympathetic system lost its vasoconstricting control in the involved area. Infiltration of the stellate ganglion failed to produce any changes on the affected side. Electric nerve baths also failed to cause any noticeable changes. If primary vascular malformations were present, the existence of multiple lesions would have to be assumed. The absence of varicosities in the authors' patient militates against the presence of any obstacle to the return flow of blood.

sympathetic functions. Therefore the authors conclude that the lesion was probably located in Clarke's column. The trophic effect of the sympathetic system, exercised through the vasomotor nerves, probably was disturbed.

SURGICAL PATHOLOGY AND DIAGNOSIS

Hogder J.: Carcinogenic Substances in Human Tissues. *Cancer Res.* 1946, 6 657

Some of the problems presented by the carcinogenic substances that have been extracted from human tissues will be solved only when these compounds have been chemically identified and assayed. At the present time very difficult questions have been raised by the fact that the substances have been found in the tissues from some patients dead because of cancer but not in others, and further in the tissues of some subjects dead because of diseases other than cancer and again not in others.

Attention is drawn to the main difficulties in this investigation: (a) the low potency of human tissue carcinogens as indicated by the prolonged latent period; (b) the sporadic occurrence of these substances; and (c) the uncertainties with regard to "susceptibility" of the experimental mice.

A technique of fractionation of unassailable material from tissues is described.

A sarcoma producing fraction has been obtained from mixed lung and kidney muscle of cancerous and noncancerous human subjects and from the liver of cancerous patients.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Koroff, D. D., Hoffman, W. S., Meyer, K. A. and Garvin, T.: High Protein Therapy; Clinical Effectiveness of Oral Administration of a New Protein Preparation as Determined by Nitrogen Balance Studies. *Arch. Surg.*, 1946, 53: 683

Maintenance of the nitrogen balance by the oral intake of various protein digests has been disappointing to date, presumably because the amount of protein digests required and their bad taste eventually proved nauseating.

This article deals with the results of maintaining a positive nitrogen balance in 14 surgical patients with a new processed protein, essenamine, which has no odor and no pronounced taste. It can be incorporated in palatable food in large quantities without disturbance of the patient's digestive system. Essenamine is a yellow white nonhygroscopic powder obtained by the partial alkaline reduction of lactalbumin. It contains 12.5 per cent nitrogen and is high in essential amino acid content.

The minimum requirements for nitrogen balance were determined by placing 11 of the 14 patients on a set diet after which all were put on the high protein intake.

In 12 experiments in which essenamine was used as the main ingredient of a high protein diet for periods ranging from 7 to 20 days, 0.52 gm. of nitrogen per kilogram per day was given orally. This diet produced positive nitrogen balances ranging from 6 to 20 gm. of nitrogen per day with an average of 12 gm. With the high essenamine intake, 52 per cent of the ingested nitrogen was excreted in the urine, 5 per cent was excreted in the feces, and 42.8 per cent was retained; this indicated the high digestibility and the high biologic value of the proteins ingested.

Both the maintenance and the high protein diet produced increases in the body weight, plasma volume, the serum protein and serum albumin concentrations and in the total circulating albumin. The diets for the minimum and high essenamine intake are appended in the original article.

STEPHEN A. ZIEGLER, M.D.

Fontaine, R. and Forester, E.: Old Ulcerated Radiodermatitis Cured by the Combined Use of Low Lumbar Sympathectomy, Saline Drip and Skin Grafts. Three-Year Follow up (Radium dermite ulcéreuse ancienne guérie par la méthode associée sympathéctomie lombaire basse, goutte-salée au sérum physiologique et greffes cutanées. Résultat de 3 ans). *Rev. chir., Par.*, 1946, 65: 277

In 1923 Cundermann reported 3 cases of ulcerative radiodermatitis cured by periarterial sympathectomy. In 1935 Lenche and Fontaine, who had used periarterial sympathectomy followed by skin graft

ing for chronic ulcers of the leg, tried this method in 2 cases of ulcer following roentgen therapy. In 1939 Lenche and Fontaine presented a review of 27 cases of ulcerative radiodermatitis, treated with sympathectomy up to that date, with 12 cures, 7 ameliorations and 8 failures. Nevertheless only a few cases have been subjected to this treatment since that date, whereas numerous other methods have been used, including the use of insulin ointment, Lactanhe serum, infrared rays, and surgical excision followed by ultraviolet irradiation or preceded by the administration of silver nitrate. Also ointments containing vitamins A and D have given good results.

However, some cases of old radiodermatitis with necrosis resist these measures, and it is for these that the author would recommend the combination of sympathectomy and skin grafting. Sympathectomy may be accomplished by local infiltration or atellar or lumbar infiltration. The sympathectomy will not suffice. It merely creates a zone of hyperemia at the level of the ulcerations. The latter must then be treated with a drip of 3/4 or 3/8 of a liter of physiological saline solution from a height of from 20 to 30 cm. into every crevice of the ulcer. This permits rapid disinfection and mechanical cleansing of the lesion which together with the hyperemia produced by the sympathectomy leads to rapid transformation of the previously torpid ulcer into a bright red granulating wound. In this condition it is in a favorable state for the reception of skin grafts, preferably of the Davis type. The resulting scar is stronger than that produced by spontaneous epidermization, which improves the late results. A case of most severe ulcerative radiodermatitis of many years' duration responded to this treatment. The patient was seen 3 years after the treatment and there had been no recurrence.

The authors stress the importance of making a biopsy examination of the ulcer area before sympathectomy is done because if malignant degeneration is present this treatment would be futile.

EDITH SCHWARTZ MOORE

Poinso, R., Charpin, J. and Deprest, A.: Case of Thoraco-brachial Nerve with Osteohypertrophy of the Entire Upper Extremity (Parkes Weber Syndrome) [A propos d'un cas de neurov thoraco-brachial avec ostéo-hypertrophie du membre supérieur droit. Syndrome de Parkes (Weber)]. *Presse Méd.*, 1946, No. 63: 865

In 1910 Klippel and Trenaunay described a condition called osteohypertrophic nerve. Practically the same disease was described by Parkes and Weber in 1918.

A 57 year old man observed by the authors had flat, extensive angiomas of purplish color which covered the right side of the chest and the right upper

extremity in addition there was hypertrophy of the involved arm, especially of the right hand. The distance from the acromion to the styloid process of the radius was 90 cm. on the right side and 86 on the left. Also the diameters of the right arm, forearm, wrist, and metacarpal region were larger on the right side than on the left. Roentgenograms showed that not only the soft tissues but also the osseous structures were hypertrophic. The cervical spine was intact.

If a flat nevus coexists with hypertrophy of the involved extremity, the condition is called Parkes-Weber syndrome,¹ while the name "Klippel-Trenaunay syndrome" is used when the angioma is associated with congenital varicosities and malformations of the face or one or more extremities.

As to the pathogenesis of the condition, variations of the genotypes subject to the mendelian law do not come into consideration. A local congenital malformation is the basis of the condition. Such a malformation may be explained by two theories: the first incriminates anomalies of the arteriovenous network, while the second considers the syndrome as the result of a congenital sympathetic lesion.

According to the first theory, vascular dystrophy is the primary lesion. Venous hypertension and an excessive blood supply produce hypertrophy of the affected limb. Abnormal arterial distribution and sometimes an arteriovenous short circuit have been demonstrated by arteriography. Surgical intervention, by diminishing the vascular malformation, permits marked decrease in the size of the angioma and of the affected extremity.

However, the second theory explains the genesis of the condition in a better way. A functional paralysis of the sympathetic system was very evident in the authors' patient in whom an acceleration of the blood flow and a diminution of the venous pressure in the involved extremity could be demonstrated. Apparently the sympathetic system lost its vasoconstricting control in the involved area. Infiltration of the stellar ganglion failed to produce any changes on the affected side. Hot and cold baths also failed to cause any noticeable changes. If primary vascular malformations were present, the existence of multiple lesions would have to be assumed. The absence of varicosities in the authors' patient militates against the presence of any obstacle to the retro flow of blood.

□ Undoubtedly the sympathetic alteration was situated in the central portion of the sympathetic system, namely the lateral horn of the spinal cord, or in the stellar ganglion. Limitation of the angiomatous to one half of the body and their metameric arrangement does not suggest a peripheral lesion of the autonomic nervous system.

The lower limit of the dorsal patches corresponded to the lower border of the cutaneous territory of the stellar ganglion. Suppression of the vasomotor function, with the presence of pilomotor reflexes and perspiration points to a central alteration because a lesion of an axial ganglion would disturb all of the

sympathetic functions. Therefore the authors conclude that the lesion was probably located in Clarke's column. The trophic effect of the sympathetic system, exercised through the vasomotor nerves, probably was disturbed.

DUCTLESS GLANDS

Sainton P., and Scliszewski A.: Thyroid Disturbances of Opposite Types in Female Twins (Réactions thyroïdiennes de sens in vers chez deux jumelles) *Ann cadec Par* 946, 7-17

This is a case report of dizygotic female twins, one of whom presented a clear case of cretinism whereas the other offered definite signs of hyperthyroidism. It is well known that there are families in which thyroid disturbances seem to be hereditary: part of the siblings presenting myxedematous and the other presenting hyperthyroid traits. In this case, the mother showed signs of slight hypothyroidism and had come from Alsace where goiter is endemic.

SURGICAL PATHOLOGY AND DIAGNOSIS

Hilger I: Carcinogenic Substances in Human Tissues. *Cancer Res* 946, 6 637

Some of the problems presented by the carcinogenic substances that have been extracted from human tissues will be solved only when these compounds have been chemically identified and assayed. At the present time very difficult questions have been raised by the fact that the substances have been found in the tissues from some patients dead because of cancer but not in others, and further in the tissues of some subjects dead because of diseases other than cancer and again not in others.

Attention is drawn to the main difficulties in this investigation: (a) the low potency of human tissue carcinogens as indicated by the prolonged latent period; (b) the sporadic occurrence of these substances; and (c) the uncertainties with regard to susceptibility of the experimental mice.

A technique of fractionation of unassailable material from tissues is described.

A sarcoma-producing fraction has been obtained from mixed lung and kidney muscle of cancerous and noncancerous human subjects, and from the liver of cancerous patients.

In all 3 cases the carcinogenic substance was found in the cholesterol-rich fraction of the unassailable material. This fraction is a crystalline mixture of compounds containing about 85 per cent cholesterol on the average.

EXPERIMENTAL SURGERY

Copp J.L.: The Role of Nuclear Physics in Medicine and Dentistry: Applications in Medicine. *J. Orthodont.*, 947 33 10

In considering the practical value of a project in research, three factors must be considered:

1. Its availability and ease of production.
 2. The half life or time for half the radioactivity to decay must be sufficiently long to permit experimentation. Ten half lives are usually considered the longest period for which an experiment can be run and in the case of the short lived isotope of carbon C^{14} this has been a serious limitation. This isotope with a half life of only 21 minutes, has been used for very important experiments but these were of necessity for very short periods.

3. The radiations should be sufficiently energetic so that they may be easily measured without recourse to complicated equipment.

Radioactive iodine may be obtained from the cyclotron or the atomic pile. It has an energetic radiation and a convenient half life of 8 days. The thyroid contains most of the iodine in the body and has tremendous powers of selective concentration. Significant amounts of radiiodine appear in the gland a few minutes after injection into rabbits. These results were confirmed in human patients. Cases of hyperthyroidism show a characteristic increase in iodine uptake and turnover, thus providing a diagnostic means for distinguishing between true hyperfunction of the thyroid gland and somewhat similar symptoms which are not due to thyroid disease. Radioactive iodine should prove of equal value in the often difficult diagnosis of myxedema and cretinism, since in these cases, there is little or no concentration of such iodine in the thyroid. There have already been studied conditions in children, diagnosed as hypothyroidic, in whom tracer studies revealed normal iodine uptake and presumably normal function of the thyroid; these patients cannot be expected to respond to thyroid treatment and other causes for their retarded development must be sought.

Since there is an uneven distribution of radioactive iodine in the thyroid gland with the heaviest concentration in the regions of overactivity hyperthyroidism may be treated by administering a dose of radioactive iodine sufficient to destroy by irradiation the overactive cells in which the concentration is high without damaging other tissue or killing the normal thyroid cells. Since, however, most thyroid cancers do not take up a significant amount of radioactive iodine this method is not applicable in the treatment of thyroid cancer.

Two radioactive isotopes of iron are suitable for biologic work. By injecting radioactive iron into dogs, it was found that the elimination of iron from the body is almost negligible. Thus the controlling factor in regulating the body stores must be absorption from the gut. Feeding experiments with radio iron have shown that absorption occurs only when there is a need as in the anemia due to iron deficiency or following hemorrhage. Patients with pernicious anemia on the contrary absorbed very little radio iron and so are not helped by its administration.

Radioactive carbon because of its short half life, can be used only for short term experiments. Despite this handicap however it has been found that when

an animal breathes an atmosphere containing C^{14} labeled carbon dioxide some of this radio carbon is actually fixed in the liver glycogen and blood sugar.

Radioactive phosphorus is easily prepared. Its radiations are easily measured and it has a convenient half life of 14.3 days. It has been used to investigate many problems in lipid and carbohydrate metabolism and for the study of bone and teeth. It has been found that the nuclei of fast growing tumors take up far more radiophosphorus than does normal tissue. Its use for the specific irradiation of these highly malignant cells was therefore suggested.

The patients selected for treatment were suffering from types of disease known to be radiosensitive—leukemia, lymphoma, myeloma, and polycythemia vera. The dose must be carefully controlled to prevent excessive destruction of the bone marrow and yet obtain effective radiation. The results on leukemic patients were, at least as good as those from intensive x ray therapy and rarely caused any radiation sickness. In most cases the white count returned to normal and the patient felt much better. The remissions were, unfortunately, only of a temporary nature.

The use of radioactive materials in medicine is still in its infancy. Progress will have to be cautious and under the control of radiologists who are aware of the great radiation hazards and are trained in the special problems of radiobiology.

SAMUEL KAHN M D

Copp H. The Role of Nuclear Physics in Medicine and Dentistry. Use of Radioactive Tracers in the Study of Bones and Teeth. *Am J Orthodontol.* 1947 33 109

Radioactive tracers should find considerable application in dental research because they provide one of the few practical methods for studying the limited metabolic activities of bones and teeth. The ease with which minute amounts of these radioactive materials may be accurately measured and distinguished from the mass of inert element in the teeth is particularly valuable. Radioactive tracers should prove useful in studying many problems of calcification and mineral exchange. They can also be used in investigating fluorosis, caries, protection, periodontal disease, root resorption, nutritional and endocrine effects, and many other dental problems.

Since, however, the effects of chronic radiation poisoning are insidious and very dangerous clinical experiments should be limited to isotopes of short half life and the dose of radioactivity should be kept as low as possible.

SAMUEL KAHN M D

Lorenz B.: Studies on Experimental Osteogenesis by Homotransplantation of Living Mucosa (Tentati di osteogenesi sperimentale con omotransplanti di mucosa viventi). *Sperimentale* 1946 95 162.

Huggins' observation that transplanted mucosa of the urinary bladder possesses osteogenic property brought up two questions.

INTERNATIONAL ABSTRACTS OF SURGERY

1. Is this property of the mucosa of the urinary bladder specific or does the mucosa of other organs display a similar effect?
2. Is homotransplantation from one individual to another as effective as autotransplantation?

The author performed a series of experiments on rabbits and dogs. A segment of the vesical mucosa 1 cm. in diameter was removed from the bladder and implanted into the aponeurosis of the rectus muscle of the abdominal wall. Specimens for histologic examination were removed at various intervals starting with the twentieth day after transplantation. The last specimen was removed between the sixtieth and seventieth days after the experiment. In no case of homotransplantation did the author succeed in producing osteogenic processes in the transplanted mucosa or adjoining tissues.

In addition to the experiments with transplantation of vesical mucosa in rabbits the author used also segments of the gastric mucosa and of the gall bladder mucosa. The results in all cases were negative.

Lorenz B: Osteogenesis of Autotransplants of Living Mucosa (Osteogenesis da autotransplanti di mucosa vivente). *Sperimentale* 1945 98 70

Heterotopic production of osseous tissue by transplanted epithelium of the urinary tract has been reported by Haggins.

The author studied the problem in dogs using trypan blue vital staining. Squar segments of gastric mucosa or mucosa of the gall bladder 1 cm. in diameter were implanted into the aponeurosis of the abdominal rectus muscle of the donor. The operations were performed under morphine-ether anesthesia and the removed portion of the mucosa were kept in a lukewarm sterile saline solution until ready for implantation. All wounds healed first in 7 days after implantation.

No osseous material could be detected at autotransplantation of the mucosa of the gall bladder or the stomach wall. On the other hand ossification was produced in all 5 dogs in which a segment of vesical mucosa was used for transplantation. The ossification processes were always most intensive at the margins of the transplanted tissues.

The author concludes from his experiments that in all probability the osteoblasts are of fibroblastic origin. They did not take the vital stain.

Baxter IL, and Moore R. H.: The Effect of the Local Reduction of Temperature on Scald Burns in the Rat. *Ann S S* 1947 15 177

A study has been made of the effects of local hypothermia on the healing of thermal burns in white rats. A moderate consistently uniform burn was produced in etherized white rats by immersion of the tail in water at 100 degrees C. Only the terminal 15 centimeters of each tail were burned. The animals were then kept in separate wire cages which permitted the tails to rest on a gauze tray. The tails of the burned rats projected into a cooling chamber through which cold air circulated, the temperature varying from 36 degrees F. to room temperature. The control rats were kept in similar cages but their tails were exposed to room temperatures varying from 75 to 80 degrees F. The tails of all surviving rats were examined grossly and histologically.

The studies indicate that hypothermia is definitely harmful to burned rats under the conditions described. An apparently immediate beneficial effect of cooling after a burn characterized by diminished swelling and necrosis gave way to extensive swelling and necrosis when the temperature was raised to room temperature. The harmful effects of cooling seem to be associated with the relaxation and distention of the blood vessels and the plugging of the lumen of many of the vessels with red blood cells. The results indicate that a permanent vasospasm occurs while the tissues are being cooled at temperatures as high as 63 degrees F. for a period of 8 hours and it is clear that a breakdown of the circulatory system can occur in tissues which are cooled but not frozen. It is noted that the lowest temperature used, 30 degrees F. resulted in the most severe damage while a temperature of 63 degrees F. for a relatively short period after burning produced only slightly more damage in the burned tails than occurred in the burned control rats in room temperature of 75 degrees F. The findings suggest that the optimum temperature for burns may be between 65 and 75 degrees F.

GYNECOLOGY AND OBSTETRICS

VOLUME 85

SEPTEMBER, 1947

NUMBER 3

CYTOLOGIC RECOGNITION OF CANCER IN EXFOLIATED MATERIAL FROM VARIOUS SOURCES

Useful Modifications of the Papanicolaou Technique

WARREN C HUNTER M D and HOWARD L RICHARDSON M D Portland Oregon

PAPANICOLAOU'S (6) investigations of desquamated vaginal epithelium began thirty years ago with a study of the morphologic and cyclic variations of cells in the vagina of the guinea pig and he first applied the technique to the diagnosis of uterine cancer in 1923 in the course of a study of human vaginal smears taken during the normal menstrual cycle. Despite this early recognition of the fact that cancers of the

uterus could thus be diagnosed, clinical men failed to see the potentialities of the method and Papanicolaou states that he lost his enthusiasm for it until he became associated with Traut (5) with whom he jointly published the monograph *Diagnosis of Uterine Cancer by the Vaginal Smear* in 1943.

The recent war years were not conducive to widespread dissemination and application of Papanicolaou's discovery, and only a few investigators have thus far had sufficient experience to enable them to publish the results of their studies. Among these are Meigs and associates, Ayre and again Papanicolaou (6).

From the Department of Pathology, University of Oregon Medical School, Portland, Oregon.

Aided by grant from the Oregon Division, American Cancer Society and by its Diagnostic Smear Laboratory, Ray S. Duham, technician.

Fig. 1. Vaginal smear. Only two cancer cells were found on the whole slide.

Fig. 2. Embedded material from same case as Figure 1. While only three cancer cells are present in the field others occurred elsewhere. Note that when concentrated by precipitation, many cells are seen and that all are in the same focal plane.

Fig. 3. Biopsy. Same case as Figures 1 and 2. Note how plainly the cancer cells in squamous cell carcinoma of the cervix are brought out in tissue stained by the Papanicolaou technique.

Fig. 4. Embedded and sectioned vaginal fluid illustrating how groups of cells often remain intact and how the pattern of tissue is preserved. These are mainly basal and precornified types of squamous epithelium.

Fig. 5. Smear of bronchial mucus. A clump of cancer cells is shown but parts of it are overlaid by cells, making the interpretation more difficult.

Fig. 6. Compare the cytology with Figure 5, which is the same case. In the embedded matter there is no doubling or folding and the cytology is excellent.

Fig. 7. Bronchial aspiration embedded. An intact segment of mucosa from a small bronchus has been obtained in an intact state.

Fig. 8. Embedded and sectioned bronchial aspiration. A portion of normal mucosa and submucosa has come off intact. Note the beautiful pseudostratification of the cells.

Fig. 9. Bronchogenic carcinoma found in bronchial mucus which was embedded and sectioned. Note the same continuity of pattern that one sees in tissue sections.

Fig. 10. Microscopic picture in mucus aspirated from the stomach. There are several normal gastric glands, separated by interglandular stroma, and one group of cancer cells. The differences between the two types is apparent.

Fig. 11. Finding in embedded mucus obtained on rectal examination. The growth was beyond the reach of the palpating finger. Histologically it proved to be an adenocarcinoma. These are cancer cells.

Fig. 12. Group of cancer cells from an instance of squamous cell carcinoma of the bladder. The cellular content of the urine was precipitated out with picric acid, filtered and embedded in paraffin.

Papanicolaou's (6) most recent communication deals not only with the smear technique as applied to uterine carcinoma, but describes its efficacy in bronchogenic, gastric, bladder and renal cancer. It now appears that the method is applicable to cancer involving or communicating with all body orifices.

As long ago as 1935 Dudgeon and Wrigley obtained a high percentage of accurate observations of bronchogenic carcinoma based on recognition of the cells in expectorated mucus, using Schaudinn's fluid as the fixative for the smears. Bamforth, 1946 employing the same technique as Dudgeon and Wrigley reports satisfactory results on freshly expectorated sputum of patients with pulmonary cancer.

To date few have attempted to modify the original Papanicolaou method of obtaining material or its preparation for study. In his last paper concerned with identification of cancer cells in other than vaginal secretion Papanicolaou (6) lists some modifications applicable to urine, gastric aspirations, and sputum. Ayre aspirates specimens directly from the cervix into a test tube rather than from the posterior fornix of the vagina, centrifuges, embeds in paraffin and stains all but the more questionable instances with ordinary hematoxylin-eosin.

Soon after we began to study vaginal fluid (November 1945) both the gynecologists and ourselves became dissatisfied with some features of the Papanicolaou technique and sought to eliminate what seemed to us to be certain inherent weaknesses. In the first place, we were unable to make good even smears by blowing the content of the glass tube on slides even though various means of smoothing out the thick areas were tried. There still remained too many dense spots and too frequent places where little or no matter was deposited. We could never convince ourselves that we were covering all fields in such smears microscopically. All too often groups of cells were overlaid by other epithelial cells or by leucocytes or there were thick patches through which we could not see well. Furthermore the time required to cover a slide an inch in width and occupied by a smear covering from 2 to 2½ inches of its length was appreciable if one really attempted to see all of it.

For the first modification most applicable to vaginal smears, we are indebted to Dr. Melvin Breese, senior resident in gynecology whose method is as follows:

1. A warm, but dry speculum, without lubricant should be used.

2. After insertion into the vagina, enough pressure should be made on the perineum to bring the speculum to as nearly a horizontal plane as possible.

3. The fluid in the posterior fornix is gently milked into the posterior blade of the instrument.

4. The speculum is carefully removed in order to retain all possible fluid.

5. A gloved index finger is dipped into the fluid and smears are made by means of two rapid, *longitudinally* directed swipes, leaving a space at one end for labelling. It is important to avoid the natural tendency to a circular motion of the finger in placing the fluid on the slide. Such smears are invariably thick and thin and are quite unsatisfactory.

5. The smear is placed directly into a jar containing alcohol-ether solution as described by Papanicolaou and Traut (5).

While this was a great improvement, we were still not satisfied, for it did not eliminate the faults inherent in any smear nor did it lessen the time required for microscopic study.

Confronted with a very thick smear made by a clinician who asked us to study his case and realizing that it would be a hopeless task, we noticed that a number of flakes had dropped off the slide into the alcohol-ether. These were recovered, embedded in paraffin cut as one does tissue and prepared with Papanicolaou's stain. The hopelessly thick portions still adhering to the slide were shaved off with a knife and handled in the same way. To our great gratification the cytologic structure was perfect and we were able to give the doctor a diagnosis of carcinoma. It was then that we first realized the possibilities of concentrating cells, lessening the space they would occupy on a slide and the saving of time that this would bring.

Turning to possible agents which would serve the dual purpose of precipitating protein and mucus and fixation of cells, we thought of saturated aqueous solution of picric acid, one

of the best precipitants of protein known and at the same time a good fixative. Furthermore, picric acid had the advantages of easy preparation, cheapness, and noninflammability.

However we soon learned that clinicians and nurses are not to be trusted to give the immediate care so necessary if cells are to be properly preserved. For some reason too probably because it stains they did not take to picric acid. For this reason we still further modified the procedure by asking that those obtaining specimens of bronchial aspirations gastric fluid rectal mucus ascitic or other fluid and urine immediately add a good quantity of 10 per cent formalin to the material. Formalin is always available and there is no excuse for not using it. This step serves to arrest cellular autolysis and at least begins the process of fixation. When the material reaches the laboratory the technician then adds a quantity of saturated aqueous solution of picric acid filters through filter paper presses the precipitate into the tip of the cone with a rod until it becomes a compact ball and then handles it like tissue by embedding in paraffin.

The results have been most gratifying. Cells of all kinds are well preserved they are concentrated obviating the necessity of long search over wide areas. The Papanicolaou stain can be employed just as successfully as with cells fixed in alcohol-ether. All cells are in the same focal plane and do not overlap one another. A number of sections can be cut and mounted on a single slide assuring an adequate sampling at different levels and affording economy in slides. We have found that for most embedded material less than five minutes is necessary to survey the section under low power and rarely more than ten minutes is required for the high power study. Finally and most important of all groups of cells are not torn apart as is very likely to happen with smearing thus enabling one to see cells in pattern and in relation to their fellows.

Vaginal fluid We generally adhere to the original Papanicolaou technique of making a smear at the time the material is obtained and of fixing it immediately in alcohol-ether. The remainder of the specimen is not discarded

however. It is carefully run into a large calibrated test tube (taped to the bottle for receiving the slide) containing 70 per cent alcohol. Or, if the gynecologist wishes, he may put the remainder directly into the alcohol-ether along with the slide. In either case care should be taken to see that the mass is kept in one piece as it slides into the fluid and that the container be handled gently so that the matter does not break up into small pieces requiring centrifugation which is extra work.

It is true that material obtained by milking out the posterior fornix with the speculum often contains sheets of cells which are probably scraped off with the instrument but this is not a disadvantage because the cells whether normal or abnormal exhibit the continuity that pathologists so much like to have. Even in smears we frequently find such sheets and in the embedded material these are still more common since there has been no opportunity for disrupting them.

Another feature requiring mention has to do with the staining qualities of cellular cytoplasm in vaginal fluids whether fixed *en masse* or in alcohol-ether or precipitated out with picric acid. In material fixed on slides in ether alcohol the cytoplasm of basal cells stain blue to brown but when fixed as tissue the different varieties of squamous epithelium stain red to pink. In our opinion this is not a drawback for one can readily recognize the different types of squamous epithelium by size and nuclear characteristics. When the method is confined to cancer study the staining reaction of the cytoplasm is of no importance.

It should also be mentioned that cells which have been embedded frequently lie on edge rather than flat as in smears. Furthermore it is common to see a clear halo or an apparent vacuole in the flat lying cells. These differences between smears and sections are quickly appreciated and are readily evaluated.

Bronchial mucus To obtain a good biopsy through the bronchoscope is often difficult and in instances where the tumor is inaccessible to the instrument, it is impossible. To the bronchoscopist then any means of obtaining additional information should be welcomed.

Thus far we have confined our observations to secretion obtained at the time of bronchos-

copy and have not worked with sputum which has been expectorated.

The means of collection of mucus is simple. The bronchoscopist saves the content of the trap which may be submitted directly to the laboratory or pours the material into alcohol ether or formalin. In our experience it is difficult to make good smears of thick mucus and we have largely given it up in favor of fixation embedding sectioning and staining with the Papanicolaou stain.

Apparently cells of all kinds are well protected and do not break down quickly in bronchial secretion a feature that does not obtain with gastric mucus, which must be fixed quickly.

It is surprising particularly in embedded mucus, how often sizeable sheets of mucosa or oesophagus are loosened by the bronchoscope and also how frequently one finds masses of bacteria clinging to dead epithelial cells like a swarm of bees. Another surprise is the frequency with which blood pigment laden monocytes are present in bronchial secretion of persons without evidence of heart failure. The bacterial flora also stands out very distinctly. There is little that need escape attention and recognition if it happens to be incorporated in mucus aspirated from bronchus.

It is not difficult to recognize bronchial epithelium whether squamous or pseudostratified columnar in groups or singly. Normal columnar cells cut longitudinally have basally placed nuclei with scattered chromatin granules and coarsely granular acidophilic cytoplasm. The more superficial cells are apt to appear quite broad and flat while the deeper ones are more typically columnar. Cells cut transversely whether singly or in masses, are likely to display little cytoplasm and thus may be mistaken for carcinoma unless weight is given to the uniformity in the size of the nuclei and the amount and distribution of the nuclear chromatin. We have found it easier to distinguish normal bronchial epithelium from carcinoma than it is to differentiate between endometrium and corporal adenocarcinoma.

By the simple procedure outlined we have been able to give valuable aid to bronchoscopists on a number of occasions. Practically always when the biopsy is positive for car-

cinoma the embedded mucus will also contain tumor cells and thus serves as a check. If the biopsy is very small or fails to include enough tumor to make it satisfactory for diagnosis, the help given by cells in mucus is very real.

A recent case will illustrate the point. A patient with an 8 centimeter sized shadow in the roentgenogram of one lung was subjected to bronchoscopy. Nothing was visible in any bronchi accessible to the instrument. A biopsy taken from the orifice of a lateral bronchus of the second order proved to be normal mucosa and submucosa. The mucus aspirated from the affected side contained enough cells to enable us to state positively that bronchogenic carcinoma was present. Pneumonec-tomy was performed and the diagnosis was confirmed both as to the existence of carcinoma and the cell type which had been found in the mucus.

Gastric aspiration. This may be obtained by passing a stomach tube preferably when the viscus is empty or at the time of gastroscopy. The gastroscopist should aspirate either from visible lesions or their vicinity whenever possible. When properly obtained and intelligently handled much valuable information can be gained from a cytologic study of gastric secretion. Heretofore the gastroscopist has had to depend upon visual observation and interpretation. Now a valuable and easily applied adjunct is at his command.

The presence of digestive ferments makes it imperative that gastric mucus be very promptly fixed, either in formalin or in picric acid solution. It is next to impossible to make thin smears of this extremely viscid mucus, and we no longer attempt to do so. Embedding and sectioning on the other hand are very satisfactory.

The cytology of gastric content is both surprising and interesting. It is amazing how often the bulk of cells or even all of them are of squamous type. Presumably these have been swallowed and come from the mouth and esophagus. As with bronchial secretion one often finds that the stomach tube or the gastro-scope detach small and intact segments of gastric mucosa.

Single normal gastric epithelial cells are columnar with clear light pink staining cyto-

plasm and rather dark but small and basally placed nuclei. Cells cut transversely seem to be almost all nucleus but uniformity in size shape and staining reaction differentiate from carcinoma. Gastric carcinoma cells are as readily identified as are those in bronchial or uterine cancer.

Urine Thus far we have studied only known instances of carcinoma of the bladder but have found as have others that the cytologic differences between normal squamous mucosa and carcinoma here is as clear cut as in other locations.

It is most important that only freshly passed urine be employed and further to inhibit cellular disintegration to add formalin solution to the specimen as quickly as possible. Picric acid is equally good if it is at hand.

We do not make smears of urine instead it is precipitated with picric acid filtered and the product embedded.

Rectal mucus Although our experience is quite limited in so far as the study of material derived from other than operative specimens of carcinoma is concerned we believe that because both normal and neoplastic epithelium is well preserved for a time in lower colonic mucus this is another location to which the smear method is readily applicable. Apparently well developed and fungating carcinomas of the colon shed many cells, often in the form of small masses which become incorporated in mucus and are easily found in sections of embedded material (Fig. 11 frontispiece).

Specimens of mucus may be obtained from the examining finger the anoscope or the proctoscope or even from the surface of a formed stool.

The normal cytology is readily established and one soon distinguishes non neoplastic cells by their columnar form uniformity in size and staining reaction of the nuclei just as in the stomach and bronchi.

Transudates and exudates Much time and effort can be saved by the simple procedure of precipitating protein from fluid with picric acid filtration embedding and sectioning.

The concentration of cells so easily obtained by this method enables one to gain a good idea of the cytology in a short space of time. We have found that the Papanicolaou

stain is as much superior to hematoxylin-eosin for cells in fluids as it is for mucus or other material.

It is common knowledge that in actinomycosis demonstration of the organism is not easy after draining sinuses have been established. Heretofore it has been necessary either to search repeatedly for the sulphur granules in pus or to curette the granulation tissue from the sinuses and section it in order to demonstrate the actinomycetes. In a case coming to our attention recently we simply took a quantity of the pus allowed it to drip into picric acid and in sections of the many masses thus obtained it was not at all difficult to find the organism.

The value of the Papanicolaou stain in the recognition of all sorts of normal and abnormal cells cannot be overemphasized. In our hands it has proved to be far superior to other tissue stains chiefly because of the striking sharpness with which the nuclei stand out as one surveys the cells under low power and the really fine nuclear detail brought out by higher magnification. Furthermore the stain is singularly free from technical difficulties and can be done by any tissue technician.

SUMMARY

1 The cytologic recognition of carcinoma in exfoliated material originally described by Papanicolaou is reliable in the hands of experienced cytologists and can be applied to a number of organs and systems of the body.

2 Not only is this method of value in the diagnosis of cancer of the uterus where it was first applied but also to carcinoma of the bladder rectum stomach and bronchus.

3 The method is a valuable adjunct to the bronchoscopist and to the gastroscopist in particular. We believe that the mucus obtained at bronchoscopy and gastroscopy should always be saved embedded and sectioned. In a number of instances already we have been able to make a positive diagnosis of bronchogenic carcinoma from cells found in the mucus when the biopsy was negative or equivocal.

4 A modification of the method of obtaining vaginal fluid which in our hands at least has proved to be easy and workable is described. Concentration of cells saves much

time in study and artifacts are practically eliminated. The Papanicolaou stain can be applied just as readily to such material as to smears.

Addendum. In our work we employ isopropyl alcohol in the ether-alcohol fixation of smears, as a solvent for certain of the stains and as a dehydrating agent. It may be presumed from his writings that Papanicolaou uses ethyl alcohol, although he does not so state.

In general it may be stated that isopropyl alcohol tends to make the cytoplasm of cells stain acidophilic which would be basophilic if ethyl alcohol were used.

When material is initially fixed in formalin, it is most important that picric acid be superimposed. Otherwise the cytoplasm of cells is prone to be deeply basophilic and does

not contrast well with the nucleus, a factor of great importance when the low power microscopic survey is being made.

TUMORS OF THE CAROTID BODY

FRANK H LAHEY M.D., F.A.C.S. and KENNETH W WARREN M.D.,
Boston Massachusetts

THE first carotid body tumor was removed by Rlegner in 1880 and described by Marchand in 1897. The carotid artery, the jugular vein, the vagus hypoglossal and sympathetic nerves were divided. The patient died on the third postoperative day. In 1866 Madyi and Ger-suny each excised a carotid body tumor with recovery of the patient. The common external and internal carotid arteries were divided in each instance with resulting hemiplegia in the case reported by Madyi. Albert in 1889 excised the first carotid body tumor without sacrifice of major vessels but the tumor recurred within 1 year. Collective reviews by Keen (1906), Reid (1920), Royster (1924), Phelps, Case, and Snyder (1931), Bevan and McCarthy (1929) and Gratiot (1943) have served to point up the many problems relating to the diagnosis and treatment of this disease. From these reviews it is reasonable to estimate that not more than 300 authentic cases of tumor of the carotid body have been recorded.

The carotid bodies first described by Von Haller in 1743 are 2 in number situated near the bifurcation of each carotid artery. Their development proceeds until the age of 20 or 30 years followed by a period of quiescence and finally by sclerosis and atrophy.

They vary in size within narrow limits but usually measure about 5 millimeters in their greatest diameter. The normal gland is gray or reddish brown in color. It is attached by a fine vasculofibrous pedicle to one of the carotid arteries usually the external from whence it derives its nutrient vessel. The structure is encompassed by a fibrous capsule from which projections penetrate the substance of the gland dividing it into lesser lobules.

The individual cells are polygonal; the protoplasm is finely granular and the large oval nucleus contains a small amount of chromatin. The cells generally are arranged in alveolar fashion. Some of the cellular elements exhibit

an affinity for the chromic salts and this feature has invited speculation about their functional relationship to the chromaffin system.

The pathology of the carotid body is limited to tumor formation. These tumors have been designated adenomas, peritheliomas, endotheliomas, hamartomas, paragangliomas, neuroblastomas and more simply, carotid body tumors. With such lack of unanimity regarding nomenclature it seems preferable to employ the latter term.

Grossly the tumors tend to retain the shape, lobulation, and encapsulation of the normal carotid body. They are firm, compressible, slow growing tumors which eventually at times encircle the carotid vessels on the affected side. They vary considerably in size with the largest tumor reported by Reid weighing 190 grams.

Microscopically according to Harrington, Clagett and Dockerty the tumors exhibit two cellular patterns occurring either alone or in combination. One pattern they designate 'alveolar' and the other 'peritheliomatous'. The former is characterized by large islands of pale polyhedral cells separated by a small amount of connective tissue. In the latter arrangement the cellular groups are smaller, irregular, and separated by an abundant vascular connective stroma. Giant and plasma cells may be found as well as areas of degeneration and hemorrhage.

Malignant manifestations such as variation in size and shape of individual cells, mitoses and invasion of the capsule and adjacent structures occur in 15 to 20 per cent of cases (Gratiot). The distinction between benign and malignant tumors of the carotid body may be difficult and it is imperative therefore that adequate biopsy specimens be secured for the pathologist.

Local metastases to regional nodes have been demonstrated but distant metastases suspected in several instances including 2 of our cases have not been verified.

Carotid body tumors while by no means common are by no means rare. They have two distinctly undesirable qualities. They become malignant in a percentage which while debatable, is disturbing. They occasionally so surround the common external, and internal carotid arteries and are so fused with them that their removal can be accomplished only by ligation of these vessels a procedure which in our experience has associated with it a mortality and morbidity which is forbidding.

While there have been numerous reports on these tumors no one has had large numbers of them to deal with since approximately 300 cases comprise the total number reported in a series of articles reviewed on the subject from 1891 to 1943.

Because of the facts stated we wish to report on 18 carotid body tumors observed at this clinic, to discuss from this experience some of their diagnostic features to make some observations upon their surgical removal and the problems involved to report upon the percentage of malignancies in our series and upon the mortality and morbidity following their removal. As the result of this experience, we would like also to present our position regarding the preparation of these patients for surgery particularly as relates to possible ligation of the carotid vessels and as to when we would or would not attempt removal of the tumor.

The four laterally located tumors of the neck which are single, discrete, and movable in character are branchial cysts, carotid body tumors, single large lateral aberrant thyroid

and neurofibromas. They are found in our experience in about the order stated in frequency of occurrence.

The most frequent differentiation which will have to be made is between branchial cyst and carotid body tumor and while this differentiation will be at times difficult, if not impossible, there are some quite distinguishing features to each of these conditions.

As anyone knows who has operated upon many branchial sinuses, these tracts are superficial in location. They are so superficial that in most instances with traction upon the fistulous opening so often at the level of the cricoid and just in front of the sternomastoid, the branchial sinus tract can be made to stand out so that it can be readily palpated directly under the skin until it disappears under the digastric muscle to connect with the lateral pharyngeal wall in the region of the tonsil. It is for this reason that branchial cysts forming as they do so frequently in the lower half of the tract are so superficial in character and located as a rule well below the level of the division of the carotid and tend as they enlarge to bulge outward upon the neck and become more and more superficial (Fig. 1).

In contradistinction to this, carotid body tumors located as they are in the carotid notch, unlike branchial cysts originate at a higher level and are more deeply located. As they enlarge, they do so upward under the angle of the jaws and at times inward until, as we have seen in 2 of our cases, they bulge into the pharynx and as happened in 1 of the cases, result in interference with swallowing (Fig. 2).

The other single laterally located neck tumor in this region which can be confused with a carotid body tumor is a single lateral aberrant

rant thyroid tumor. Lateral aberrant thyroid tissue originating from the ultimobranchial bodies at the beginning of the seventh week of the embryo is set free from the pharynx and develops contact with the two lobes of the thyroid. In occasional cases the ultimobranchial bodies become converted into thyroid tissue and form either a single lateral mass or masses located in front of the sternomastoid muscle along the course of the internal jugular vein. When these are multiple gland-like structures, as they most frequently are, there is no question of their being con-

fused with a carotid body tumor. When however, they occur as a single discrete, laterally located movable tumor mass, as they occasionally do they can and have been confused with a carotid body tumor. Such a single lateral aberrant thyroid tumor occurred in 1 of our patients in whom we removed a carotid body tumor from the other side and was mistakenly diagnosed by one of us (F.H.L.) as a bilateral carotid body tumor until removed and sectioned. These tumors are often fairly deep in location discrete in character movable, and differ from carotid body tumors only

Fig. 2. All three of the patients in this illustration have carotid body tumors. Note that they are of deeper origin,

enlarge inward, and originate higher than do the usual branchial cysts.

Fig. 3. This illustration shows a patient with discrete lateral aberrant thyroid tumor. Note that similar to carotid body tumors this tumor is deep in origin and is situated high, and is often difficult to differentiate from carotid body tumor.

Fig. 4. This illustration shows a patient with a discrete lateral aberrant thyroid tumor which has become malignant. Note that tumors of this type can enlarge superficially and occupy the region usually occupied by brachial cysts.

in that they do not tend to enlarge upward under the jaw (Figs. 3 and 4).

Neurofibromas can of course occur anywhere and in our experience have occasionally been found in the neck. Arising as they do from nerve tissue anywhere, they have as characteristics only laterally located discreteness and movability and no typical features by which they may be distinguished from these other conditions.

While in many cases it is possible to be reasonably sure of the diagnosis of carotid body tumor it is of importance from the point of considering preoperatively the possibility that to accomplish successfully the removal of a carotid body tumor should it prove such, one must always have in mind that ligation of the common carotid internal and external carotid arteries may be necessary. With this possibility in mind and particularly in the light of the experience Drs. Poppen and Horrax in the neurosurgical department of this clinic, have had with 100 cases of intracranial aneurysm with ligation of the internal carotid neck in 75 cases (in 25 cases, intracranial operations were carried out) no one today

considers approaching the exploration of a carotid body tumor without preliminary compression of the carotid on the side of the neck on which the tumor is until by pressure complete obliteration of the carotid for a period of 10 minutes 3 times daily can be endured by the patient with complete absence of symptoms.

In the surgical approach to any single, discrete, movable high and laterally located tumor of the neck we strongly urge that this preliminary carotid compression be employed. We do not believe that it is possible to be certain that any such neck tumor may not on exposure, prove to be a carotid body tumor. If it does prove to be a carotid body tumor requiring consideration of whether or not to interrupt the carotids it at least is some comfort to know that cerebral symptoms do or do not occur with the employment of complete carotid compression for a period of 10 minutes 3 times a day.

out producing cerebral damage and a fatality, has only relative value. It is of value only when it is positive in the production of symptoms during the compression and has not in our hands proved dependable on the negative side when symptoms are not produced by compression. We have had disaster result when such compression could be borne with no symptoms whatever and so we have placed dependence upon it solely if it is positive and symptoms are produced.

We have employed mechanical compression with the Richard light pressure apparatus and also digital compression endeavoring to be certain of the completeness of the compression by the absence of a temporal pulse and by the complete absence of a carotid pulse when the compression has been of the digital character.

In spite of the fact that such compression could be borne without symptoms fatalities occurred in 2 of 6 patients with carotid body tumor in whom ligation of the common external and internal carotid arteries was necessary in order to remove the tumors successfully. It seems probable to us from this experience that the ability of a patient to withstand carotid compression for 10 minutes 3 times a day is not a dependable indication that the common internal and external carotid arteries can be ligated with safety if it is necessary to do so to remove the tumor. It has value only as evidence should the tumor be malignant or of the type which completely surrounds the common external and internal carotid arteries and will require ligation of all of these vessels. A catastrophe may be expected in a high percentage of cases in which it is done.

Whether this test is or is not dependable as a test of a patient's ability to withstand common external and internal carotid ligation because it is impossible by means of digital pressure or mechanical pressure apparatus completely to obstruct the blood flow through the carotid or because the compression can not be complete for a long enough period for a true test we are unable to say. The fact however that 2 fatalities have occurred in patients who could stand it without symptoms does not give us confidence to ligate the carotids based upon absence of symptoms with this test.

It is to be noted in this series that 4 of these carotid body tumors were completely removed without the necessity of ligating the carotid arteries but that of these 4 cases 1 patient died. An autopsy was obtained in this case and attention should be directed to the finding in this case of one of the dangers in the removal of these tumors even when they can be completely extirpated without the necessity of carotid ligation. Autopsy showed that although the carotid body tumor had been ablated without injury to the carotids a sclerotic plaque had been so displaced from the intima in the manipulation of the vessel that complete carotid thrombosis and a fatality resulted.

From the above experiences what should be the treatment of a carotid body tumor?

The ideal treatment of carotid body tumor is complete surgical excision. The hazards of total extirpation which derive from the necessity of ligating the carotid vessels in approximately 50 per cent of cases in which total excision is practiced is such as to justify not employing this procedure. In an effort to formulate a rational routine of decision in this condition there are certain factors relative to the clinical and pathologic nature of the disease as well as to the risks of surgical excision and the effectiveness of alternative therapy which should be kept in mind.

In approximately 75 per cent of cases the tumor is entirely asymptomatic the presence of the cervical swelling being the only evidence of the disease. The symptoms in the remaining 25 per cent are usually trivial and only rarely are these tumors attended by serious manifestations such as syncope. Finally the lesion grows very slowly in most instances.

Pathologically it is estimated that 15 to 20 per cent of carotid body tumors are malignant. Only Harrington Clagett, and Dockerty disagree materially with this conclusion in reporting an incidence of malignancy of 50 per cent. In the material observed at the Lahey Clinic there was no proved instance of malignancy in the 18 cases.

Malignancy when it does occur is of low grade. Local nodes are invaded but distant metastases suspected in a few cases, have never been verified.

Recurrence is estimated to be 7 per cent, but again Harrington, Clagett, and Dockerty reported 2 recurrences in 8 survivors following excision of malignant tumors of the carotid body a recurrence rate of 25 per cent. It is pertinent to note that these 2 patients lived 8 and 10 years respectively after operation had been carried out.

The consequences of surgical excision are often serious. Phelps, Case and Snyder reviewing 154 proved cases, of which 148 were operated upon, reported a mortality of 24 per cent. The mortality was 30 per cent in the group of patients in whom carotid ligation was necessary. Seven per cent of those who recovered following ligation of the carotid artery had cerebral complications.

In our group of 18 cases 17 patients complained of a swelling in the neck while only 1 victim was unaware of the cervical tumor which was discovered during a routine physical examination. In 13 instances the tumor had gradually increased in size. Five patients had pain in the neck or face 3 experienced hoarseness, and 1 complained of dysphagia. There was a firm tumor below the angle of the jaw in every instance. The two sides were affected almost equally there being 8 tumors on the right 7 on the left and 3 were bilateral. The sexes were likewise affected equally. A thrill and bruit were definitely recorded in 3 cases and in each of these instances the tumor was compressible. Cranial nerve damage was evident in 2 patients the hypoglossal nerve being involved in 1 case and the recurrent laryngeal nerve in another. In 2 patients the carotid body tumor had enlarged inwardly so that it bulged into the pharynx. In 1 of these the intrapharyngeal enlargement was of such extent as to interfere with swallowing and nutrition. This patient an Army officer had had two attempts at removal of the tumor in the Army one by an external approach and one by an approach through the pharynx. Both were unsuccessful and the patient came to the clinic for further trial because of his inability to eat. The tumor was successfully removed by combined external and intrapharyngeal approach. With no attempt to enlarge upon the difficulty of the operation but to record the height to which these tumors can extend

up under the jaw it was finally removed only by detaching it from the base of the skull.

In the 18 cases observed at the clinic, the correct preoperative diagnosis was made in 9 instances an accuracy of 50 per cent. The lesion was thought to be a branchial cyst in 5 cases, tuberculous adenitis in 2 patients, and a lymphoma and neurofibroma, respectively in 2 individuals. It is interesting to record that in 1 patient in whom the clinical diagnosis of bilateral carotid body tumor was made, such a tumor was found at operation on the right and a lateral aberrant thyroid mass was removed from the left. Punch biopsy advocated by some, is unsafe and uncertain.

Generally speaking carotid body tumors cause no subjective complaints. Their growth is so gradual and their presence is so symptomatically benign that patients seek medical care late. In most recorded series the mean duration of symptoms before operation is 6 years and in extreme instances the tumor has been present for 35 years. The duration of symptoms in our cases varied from 3 months to 16 years.

Despite the paucity of symptoms which usually attend these tumors, a wide variety of signs and symptoms may occur. They result from stimulation or invasion of contiguous cervical structures such as the esophagus, pharynx, vagus, laryngeal, or the sympathetic nerves.

Of the 18 patients operated upon at the clinic, excision of the tumor without ligation of the carotid vessels was accomplished in 5 cases. Excision of the growth with ligation of the common internal and external carotid arteries was performed in 6 instances. The external carotid artery alone was interrupted in 2 individuals. The tumor was not excised in 5 patients subjected to operation because complete removal of the growth would have required carotid ligation. Subtotal resection was done in 1 instance, simple exploration in 2 and biopsy in 2 others.

There was 1 fatality in the group of 4 patients in whom the tumor was excised without sacrifice of major vessels, a percentage of 25. Death was due to thrombosis of the internal carotid artery. Two deaths occurred among the 6 patients subjected to ligation of the com-

Fig. 5. This illustration and Figure 6 show carotid bodies so surrounding the external, internal, and common carotid arteries that ligation of all three vessels was necessary. Note how completely this tumor envelops all three vessels. It is in this type of carotid body tumor that removal, with the risk involved in ligating all three vessels, is unjustifiable.

Fig. 6. See Figure 5. Note the complete involvement of the vessels (shown with rods in them).

mon, internal, and external carotid vessels a mortality of 33 per cent. The tumors were benign in each fatal instance.

Two of the 4 patients who recovered following ligation of the carotid arteries had temporary hemiplegia with minimal residual symptoms. No mortality attended the group submitted to simple exploration, biopsy, or subtotal excision.

Eighteen patients were subjected to surgery, and there were 3 deaths, a mortality of 16.6 per cent. The 3 deaths occurred in the group of 13 patients in whom the tumor was completely excised, giving a mortality for surgical extirpation of 23 per cent.

The results of alternative therapy are not encouraging. Bevan and McCarthy recorded a good response to irradiation of a carotid body tumor which was explored but not removed, and advocated conservative treatment for benign carotid body tumors whose removal would necessitate the ligation of the carotid arteries. Phelps, Case, and Snyder contrarily state that of 7 proved cases of carotid body tumor treated with x-rays, radium, or both, the patients failed to derive any appreciable benefit from this mode of treatment. Three patients in the clinic series were given radiation therapy with slight reduction in size of the tumor in each instance.

With all of the above facts in mind, we believe that either when the preoperative diagnosis of carotid body tumor has been correctly

made or when such a tumor is demonstrated in exploring a tumor of undiagnosed origin, if the carotid body tumor is found to surround the internal, external, and common carotids completely, removal by ligation of the common carotid and internal and external carotids should be done only when biopsy demonstrates the tumor to be truly of a malignant character (Figs. 5 and 6). Even then it should be removed only when the patient has been able to work up to complete carotid compression for a period of 10 minutes 3 times a day without symptoms, and when friends and family are aware of the risks involved in such a procedure. Ligation of the common, internal, and external carotids when done should be accompanied by ligation of the internal jugular; the patient should be kept in the head-down position and in an oxygen tent for a considerable period of time after operation.

When tumors of the carotid body are small, do not surround the vessels, and can be extirpated without damage to those structures, removal is justifiable. When carotid body tumors in their enlargement project into the pharynx by bulging the pharyngeal wall inward so that they interfere with swallowing, an attempt must be made to remove them. In neither of the 2 cases in this group in which the tumor bulged into the pharynx was there involvement of the carotids, and in both cases it was possible to extirpate the tumor without ligation of the carotid vessels.

In all cases in which the tumor as shown in Figures 5 and 6 so surrounds the carotids that ligation of all these vessels will be necessary the mortality of this procedure is such as not to justify its removal.

It is to be noted that our diagnoses were correct in only 50 per cent of these 18 cases. It is, therefore, evident that some of the tumors thought to be carotid body tumors will prove not to be and that some of the tumors thought not to be carotid body tumors will prove to be carotid body tumors. For these reasons we believe that since aberrant thyroid tumors which can closely simulate carotid body tumors, are frequently malignant and since branchial cysts can so readily be re-

moved and since some carotid body tumors can be demonstrated by exploration to be safely removable all laterally located discrete, and movable neck tumors should be explored.

THE ROLE OF CHRONIC THROMBOSIS OF THE PORTAL VEIN AND ITS TRIBUTARIES IN THE SYNDROME OF SPLENIC ANEMIA

MAVIS P. KELSEY M.D., HAROLD E. ROBERTSON M.D. and
HERBERT Z. GIFFIN M.D. Rochester, Minnesota

THROMBOSIS of the splenic and portal veins and splenic anemia, or Banti's syndrome are often seen together in the same patient. Despite numerous investigations the causal interrelationships of the two processes are still not understood. The problem has assumed new importance now that some relief may be offered to patients so afflicted. Until recently the only corrective measures available for relief of portal congestion in these cases were splenectomy, omentopexy and injection of esophageal varices by means of the esophagoscope. Splenectomy is only partially effective, since it reduces the portal blood flow by only 20 per cent (11). The value of omentopexy and injection of esophageal varices has been equivocal at best and these procedures are rarely used. Most recent efforts to combat portal obstruction are by splenorenal and portocaval anastomosis as advocated by Blakemore and Lord or by extensive gastric resection as described by Baronofsky and Wangensteen.

Splenic anemia or Banti's syndrome, as Banti finally described it in 1910, was thought to be the result of an undiscovered infectious agent brought to the spleen by the arterial blood to produce splenomegaly and passing on to cause sclerosis in the splenic and portal veins and cirrhosis of the liver. The anemia and leucopenia were thought to result from depression of the activity of bone marrow by the toxic agent. The characteristic microscopic finding in the spleen was fibroadenoma or fibrosis of the pulp and Malpighian bodies

with retention of the normal glandlike structural appearance.

Several diseases including Gaucher's disease (9), chronic hemolytic anemia (12) and some forms of leucemia (5, 17) have been segregated as specific entities from splenic anemia while dozens of suggestions have been advanced as to the etiology and pathogenesis of the remaining large number of unsolved cases. We can divide these suggestions into 3 groups each with numerous variations. First is the suggestion similar to that of Banti that the spleen is involved primarily, the changes in the veins and liver occurring secondarily as a result of liberated toxins (13). Ravenna's idea of a primary active congestion in the spleen and Pemberton and Kiernan's idea of an intrasplenic arteriovenous shunt may be included in the first group. Second is the suggestion that the spleen has a secondary rôle. This considers the process either to be a simple obstructive congestive splenomegaly (4, 16) or to be a concomitant manifestation of hepatic disease (9). Third the most reasonable suggestion is that splenic anemia is a symptom complex common to a miscellaneous collection of diseases in which the spleen has either a primary or a secondary rôle (6, 10). These diseases include splenoportal thrombosis, hepatic cirrhosis and chronic infectious splenomegaly.

Several important questions arise when one attempts to decide which of these assumptions is most tenable. What is the actual cause of the splenic and portal venous disease seen in many cases of splenic anemia or Banti's syndrome? It is important to know if these venous changes are secondary to toxins or thrombogenic agents liberated by the spleen, as first postulated by Banti, or if they result from causes completely unrelated to the spleen. If

In several cases (two or more possible causes for involvement of the portal veins) were present.

the causes are unrelated to the spleen does the obstruction and congestion caused by chronic splenic and portal thrombosis produce the splenomegaly? For comparison does the portal congestion encountered in cases of hepatic cirrhosis cause splenomegaly or does pure chronic passive congestion encountered in cases of prolonged heart failure cause splenomegaly? Finally what is the incidence of portal congestion and what are its causes in cases in which the clinical diagnosis is splenic anemia?

METHOD

In an effort to answer these questions we have made a clinical and pathologic analysis of data on several groups of cases in which necropsy was performed. There were 61 unselected cases of chronic disease of the splenic or common portal vein in which the disease had lasted 6 months or longer (62 per cent were males, age range 17 to 82 years). One hundred consecutive cases of hepatic cirrhosis (70 per cent were males, age range 12 to 72 years) were divided into the following groups: 26 with intrahepatic portal obstruction, 25 without evidence of intrahepatic or other portal obstruction and 49 unsuitable for study owing to inadequate data or to the presence of other factors which influenced splenic size. Twenty cases of heart disease were selected in

which the patient had died after 2 or more years of chronic congestive heart failure (males, 65 per cent, age range 17 to 76 years). There were 30 cases with the clinical diagnosis of splenic anemia which after pathologic study still met all the general criteria of Banti (males, 67 per cent, age range, 10 to 62 years).

RESULTS AND COMMENT

Pathology of chronic disease of the portal veins. No clinical or pathologic evidence was found to support the thesis of Banti that chronic disease of the splenic and common portal veins is caused by toxins liberated by the spleen. Instead we found some other positive or probable cause for the chronic venous disease in 48 of the 61 cases. In most instances the cause was unrelated to the spleen. Even in 7 of the 14 cases in which a clinical diagnosis of splenic anemia had been made a well established cause completely unassociated with the spleen could be found to account for the thrombosis.

As Table I shows, there were some cases in which more than one cause was present. For example, several patients who had cirrhosis underwent surgical exploration which involved manipulation of the portal vessels. The surgical procedures were usually for disease of the biliary tract or the appendix but in one case persistent ascites developed 2 weeks after thyroidectomy and at necropsy 2 years later typical chronic thrombotic changes were observed in the portal veins. In nearly all cases of malignant lesions the growth had invaded the veins and secondary thrombosis had occurred. In several instances of disease of the biliary tract inflammation was actually seen to spread from the common bile duct to the portal vein. Similar spread of inflammation to the veins was seen in cases in which duodenal ulcer or pancreatitis was present. Pylephlebitis is usually thought to be a rapidly fatal disease but one of these patients survived for 11 years after an acute phase of the disease to present a classic picture of splenic anemia. Pylephlebitis is probably a more frequent cause of chronic portal venous disease than is realized. Patients who have chronic congestive heart failure usually have an associated abdominal disease which also participates in the formation of thrombi. Omphalitis in infancy may

account for many of the cases of splenic anemia appearing in early childhood

Chronic progressive thrombosis is the most common type of pathologic change in the veins. There were 39 such cases among the 53 in which microscopic sections were available. Without going into the controversy concerning pathogenesis of clot formation these lesions were predominantly thrombotic in 28 cases and predominantly phlebotic in 11.

The thrombotic vessels displayed an extremely chronic intimal thickening. Usually eccentrically placed and constricting or obliterating the lumen, the process arose from intimal proliferation and organization of thrombi. Canaliculi and deposits of iron were usually present to indicate the thrombotic origin of this change. The media was thickened showing a cellular response where there was overlying recent thrombosis. Muscle fibers were replaced in great part by fibrous tissue. The adventitia also was thickened by an abnormal amount of fibrous tissue and free cells. In the phlebotic group the process was predominantly inflammatory characterized by polymorphonuclear cellular infiltration. Thrombotic clots were completely overshadowed by suppuration in 2 cases of protracted pylophlebitis. In addition there were cases depicting all degrees between almost pure thrombosis and almost pure suppuration.

Eight cases fit the often quoted descriptions (7) of phlebosclerosis and were probably the result of ancient thrombosis as evidenced by scarring of the media and adventitia, the presence of canaliculi and iron deposits and the finding in proved thrombosis of venous segments which are identical to phlebosclerosis. Although there was no substantiating evidence in some of these cases the changes may have been the result of developmental stenosis of the portal vessels.

The technical difficulties of vascular surgery and the fertile soil for postoperative thrombosis in most of the cases are obvious. The process was usually progressive with repeated thromboses superimposed one on the other and showed various stages of organization in different segments of the veins. Furthermore in only a few cases was the disease limited to the splenic or the common portal

vein; it usually extended to involve two or more major veins or into the smaller collateral veins obstructing them and exaggerating the portal obstruction. Incidence of venous involvement was as follows: common portal 46 cases, splenic 44, intrahepatic branches 41 and mesenteric, 23.

Cavernomatous transformation was a finding associated with both the thrombotic and the phlebosclerotic vessels and was interpreted as new formed collateral circulation. Neoplastic obstruction was seen in 5 cases. In only 1 case that of an 82 year old man was there a small primary atherosclerotic obstruction which involved the splenic vein. Superimposed terminal thrombosis was seen in 43 cases.

Splenomegaly in chronic splenoportal venous disease. Of the 61 cases of chronic disease of the portal veins, 44 were suitable to study the effect on the spleen of chronic venous obstruction. It was found that 73 per cent of the spleens were enlarged and the mean weight was 685 grams, even though there was an extremely wide range. For those cases in which there was splenic enlargement no cause outside of venous obstruction could be found to account for the enlargement. Associated cirrhosis or toxemia of infection could have caused it in only a few cases. Why then were not all the spleens enlarged? Because several factors in addition to portal congestion influenced the size of the spleen. First the presence of old infarcts with parenchymal destruction definitely prevented enlargement in two or more cases. One of these spleens weighed 35 grams and was composed chiefly of scar tissue. Second there tended to be less enlargement among the older patients owing to their naturally diminished splenic function and blood flow. In 3 cases of complete splenic venous obstruction in which the patients were more than 73 years of age no collateral circulation, splenomegaly or other evidence of portal congestion developed. Third in cases of minimal portal obstruction or well developed collateral circulation there was less enlargement. Fourth and most important was the duration of obstruction for in 11 cases in which the duration could be reasonably determined to be less than 2 years the splenic

In several cases two or more possible causes for involvement of the portal veins were present.

the causes are unrelated to the spleen does the obstruction and congestion caused by chronic splenic and portal thrombosis produce the splenomegaly? For comparison does the portal congestion encountered in cases of hepatic cirrhosis cause splenomegaly or does pure chronic passive congestion encountered in cases of prolonged heart failure cause splenomegaly? Finally what is the incidence of portal congestion and what are its causes in cases in which the clinical diagnosis is splenic anemia?

METHOD

In an effort to answer these questions we have made a clinical and pathologic analysis of data on several groups of cases in which necropsy was performed. There were 61 unselected cases of chronic disease of the splenic or common portal vein in which the disease had lasted 6 months or longer (62 per cent were males age range 17 to 82 years). One hundred consecutive cases of hepatic cirrhosis (70 per cent were males age range, 12 to 72 years) were divided into the following groups: 26 with intrahepatic portal obstruction, 25 without evidence of intrahepatic or other portal obstruction and 49 unsuitable for study owing to inadequate data or to the presence of other factors which influenced splenic size. Twenty cases of heart disease were selected in

which the patient had died after 2 or more years of chronic congestive heart failure (males, 65 per cent age range 17 to 76 years). There were 30 cases with the clinical diagnosis of splenic anemia which after pathologic study still met all the general criteria of Banti (males 67 per cent age range, 10 to 62 years).

RESULTS AND COMMENT

Pathology of chronic disease of the portal veins

No clinical or pathologic evidence was found to support the thesis of Banti that chronic disease of the splenic and common portal veins is caused by toxins liberated by the spleen. Instead we found some other positive or probable cause for the chronic venous disease in 48 of the 61 cases. In most instances the cause was unrelated to the spleen. Even in 7 of the 14 cases in which a clinical diagnosis of splenic anemia had been made a well established cause completely unassociated with the spleen could be found to account for the thrombosis.

As Table I shows there were some cases in which more than one cause was present. For example, several patients who had cirrhosis underwent surgical exploration which involved manipulation of the portal vessels. The surgical procedures were usually for disease of the biliary tract or the appendix but in one case persistent ascites developed 2 weeks after thyroidectomy and at necropsy 2 years later typical chronic thrombotic changes were observed in the portal veins. In nearly all cases of malignant lesions the growth had invaded the veins and secondary thrombosis had occurred. In several instances of disease of the biliary tract, inflammation was actually seen to spread from the common bile duct to the portal vein. Similar spread of inflammation to the veins was seen in cases in which duodenal ulcer or pancreatitis was present. Pylephlebitis is usually thought to be a rapidly fatal disease but one of these patients survived for 11 years after an acute phase of the disease to present a classic picture of splenic anemia. Pylephlebitis is probably a more frequent cause of chronic portal venous disease than is realized. Patients who have chronic congestive heart failure usually have an associated abdominal disease which also participates in the formation of thrombi. Omphalitis in infancy may

account for many of the cases of splenic anemia appearing in early childhood

Chronic progressive thrombosis is the most common type of pathologic change in the veins. There were 39 such cases among the 53 in which microscopic sections were available. Without going into the controversy concerning pathogenesis of clot formation these lesions were predominantly thrombotic in 28 cases and predominantly phlebotic in 11.

The thrombotic vessels displayed an extremely chronic intimal thickening or eccentrically placed and constricting or obliterating the lumen the process arose from intimal proliferation and organization of thrombi. Canaliculi and deposits of iron were usually present to indicate the thrombotic origin of this change. The media was thickened showing a cellular response where there was overlying recent thrombosis. Muscle fibers were replaced in great part by fibrous tissue. The adventitia also was thickened by an abnormal amount of fibrous tissue and free cells. In the phlebotic group the process was predominantly inflammatory characterized by polymorphonuclear cellular infiltration. Thrombotic clots were completely overshadowed by suppuration in 2 cases of protracted pyelophlebitis. In addition there were cases depicting all degrees between almost pure thrombosis and almost pure suppuration.

Eight cases fit the often quoted descriptions (7) of phlebosclerosis as evitably the result of ancient thrombosis as evidenced by scarring of the media and adventitia, the presence of canaliculi and iron deposits and the finding in proved thrombosis of venous segments which are identical to phlebosclerosis. Although there was no substantiating evidence in some of these cases the changes may have been the result of developmental stenosis of the portal vessels.

The technical difficulties of vascular surgery and the fertile soil for postoperative thrombosis in most of the cases are obvious. The process was usually progressive with repeated thromboses superimposed one on the other and showed various stages of organization in different segments of the veins. Furthermore in only a few cases was the disease limited to the splenic or the common portal

vein it usually extended to involve two or more major veins or into the smaller collateral veins, obstructing them and exaggerating the portal obstruction. Incidence of venous involvement was as follows: common portal 46 cases, splenic 44, intrahepatic branches 41 and mesenteric, 23.

Cavernomatous transformation was a finding associated with both the thrombotic and the phlebosclerotic vessels and was interpreted as new formed collateral circulation. Neoplastic obstruction was seen in 5 cases. In only 1 case that of an 82 year old man was there a small primary atherosclerotic obstruction which involved the splenic vein. Superimposed terminal thrombosis was seen in 43 cases.

Splenomegaly in chronic splenoportal venous disease. Of the 61 cases of chronic disease of the portal veins 44 were suitable to study the effect on the spleen of chronic venous obstruction. It was found that 73 per cent of the spleens were enlarged and the mean weight was 685 grams even though there was an extremely wide range. For those cases in which there was splenic enlargement no cause outside of venous obstruction could be found to account for the enlargement. Associated cirrhosis or toxemia of infection could have caused it in only a few cases. Why then were not all the spleens enlarged? Because several factors in addition to portal congestion influenced the size of the spleen. First the presence of old infarcts with parenchymal destruction definitely prevented enlargement in two or more cases. One of these spleens weighed 35 grams and was composed chiefly of scar tissue. Second there tended to be less enlargement among the older patients owing to their naturally diminished splenic function and blood flow. In 3 cases of complete splenic venous obstruction in which the patients were more than 73 years of age no collateral circulation splenomegaly or other evidence of portal congestion developed. Third in cases of minimal portal obstruction or well developed collateral circulation there was less enlargement. Fourth and most important was the duration of obstruction for in 11 cases in which the duration could be reasonably determined to be less than 2 years the splenic

mean weight was 215 grams while in 31 cases in which obstruction had lasted for 2 years or longer the mean weight was 910 grams.

The histologic appearance of the spleens in most of the cases was uniformly alike and was remarkably similar to that of so called splenic anemia or Banti's syndrome. Fibrosis of pulp and malpighian bodies with retention of normal architectural structure was seen in both large and small spleens. Reticuloendothelial hyperplasia and perimalpighian fibrosis were more common in the larger than in the smaller spleens.

Splenomegaly in cirrhosis and in heart failure Cirrhosis of the liver when associated with portal congestion produces a high incidence of splenomegaly (mean splenic weight, 544 grams). This is shown in 85 per cent of the 26 cases where definite evidence of intrahepatic portal obstruction was found. Portal congestion was determined in these cases by the history of gastroesophageal hemorrhage and ascites and the presence of increased collateral circulation.

McIndoe pointed out that portal obstruction in cirrhosis results from derangement of the intrahepatic portal veins by growth of hyperplastic liver cells. The obstruction may be complete long before hepatic function is appreciably diminished so that in some cases of mild cirrhosis there is severe portal congestion. This was true in 5 of these 26 cases. Four spleens were not enlarged in spite of distinct portal congestion and no cause was found to explain this. Contrary to Rousselot's opinion the degree of obstruction did not always determine the degree of splenomegaly.

Histologic changes in the spleens in most of these cases were similar to or identical with those of chronic portal venous disease or splenic anemia.

In the 25 cases of cirrhosis in which no evidence of portal obstruction was found the mean weight of the spleens was only 281 grams. The lack of obstruction in these cases may be explained in 20 cases by the slight degree of cirrhosis. Since severity of cirrhosis and severity of portal obstruction are usually of about the same degree it is difficult to determine whether the cirrhotogenous toxins acting on splenic parenchyma or the portal obstruc-

tion plays the principal rôle in splenomegaly. Apparently as McMichael believed, both factors play a part. Histologically these spleens usually showed the early signs characteristic of splenic anemia. Some congestion was seen although there was no evidence of it elsewhere in the portal system. Perhaps the short duration of the disease also played a large part in the lack of marked splenomegaly.

Congestive heart failure of long standing failed to produce appreciable splenomegaly (mean splenic weight 194 gm.) even though the histologic changes were those of marked chronic passive congestion and often simulated the picture of splenic anemia. These findings seem to indicate that chronic passive congestion *per se* is not a cause of marked splenomegaly. Perhaps in order to cause splenomegaly the portal pressure must be higher than that produced by heart failure, the congestion must be active instead of passive or there must be a high differential between portal and systemic venous pressures.

Cases in which the diagnosis was splenic anemia In the vast majority of the 30 cases in which the clinical diagnosis of splenic anemia had been made portal congestion was present. From this group with congestion it will be seen that the surgeon may expect to find chronic venous disease in half the cases (14) and cirrhosis in almost as many (11). The 14 cases in which there was venous disease have already been described among the 61 cases in which there was chronic disease of the portal veins. Many of these 61 cases were alike both clinically and pathologically whether diagnosed splenic anemia or not. Also in the group of 100 cases in which there was hepatic cirrhosis the cases with splenomegaly were similar to the 11 cases of splenic anemia with cirrhosis. As previously shown histologic changes in the spleen are usually the same for splenic anemia, cirrhosis and chronic disease of the portal veins.

These findings indicate that the changes form a pattern which may appear in response to more than one cause. When cirrhosis or chronic portal venous disease is manifested clinically by splenomegaly and by anemia and leucopenia as a result of secondary splenic overactivity the diagnosis of splenic anemia

is often made. It is easy to make a diagnosis based on such findings whereas it would be difficult to discover the underlying process.

In 3 instances of splenic anemia there was congestion with no apparent portal obstruction. These may be examples of a unique disease. The hypothesis of Pemberton and Kiernan that the portal congestion is a result of intrasplenic, arteriovenous shunt may explain these cases. Determinations at the time of operation, of blood flow through the spleen may provide valuable information on this hypothesis. The 2 remaining cases of splenic anemia had no portal congestion or obstruction and demonstrate something we must not forget that the syndrome of splenic anemia may be produced in an occasional patient by cause other than portal congestion.

CONCLUSIONS

A well established cause outside the spleen can be found to account for chronic disease of the splenic or portal veins in most cases. No evidence was found which indicated that toxins liberated by the spleen cause the venous disease.

The most common type of lesion in the veins in chronic disease of the portal vein is chronic thrombosis. In the cases of severe so-called phlebosclerosis the condition is the result of ancient thrombosis. Neoplastic invasion occurs in a few instances and atherosclerosis in a rare case.

In the majority but not all of the cases of chronic disease of the splenoportal veins splenomegaly is associated. Several factors other than portal obstruction influence the size of the spleen in these cases. Those which tend to limit the degree of splenic enlargement

are splenic infarction with parenchymal destruction advanced age of the patient well developed collateral circulation and brief duration of the obstruction.

Cirrhosis of the liver often produces splenomegaly and the complete clinical picture of splenic anemia, but the pure chronic passive congestion of prolonged heart failure does not produce splenomegaly.

Splenic anemia is not a specific disease entity. The syndrome can be produced by a number of diseases, the most common are chronic splenoportal thrombosis and hepatic cirrhosis.

EARLY MOBILIZATION OF PATIENTS AFTER MAJOR SURGICAL PROCEDURES

NELSON W. CORNELL, M.D. F.A.C.S. and DAVID T. W. LIN, M.D. New York, New York

THE idea of early ambulation following major surgical procedures is not new. Ries in 1899 was probably the first surgeon to practice this type of treatment in the country. Leithauser and Bergo (6) in 1941 reported a series of 383 appendectomies with an average postoperative confinement to bed of 15 days. In 1943 Leithauser (5) reported 464 consecutive major surgical procedures (including 274 appendectomies) in which all patients were ambulated in the first 24 hours. Schafer and Dragstedt, Ashkins, and Steinhart have added further cases to the long list. There are many reports in foreign literature, one of the more noteworthy being that of Kimbarovsky whose experience covered 551 cases. Many of his patients walked from the operating table.

Since January 1945 we have been mobilizing our private patients early after operation. Excluding hemorrhoidectomies, excision of small tumors, fractures, spine fusions, cases and the like, there were between January 1945 and March 1946 66 unselected consecutive cases of major surgical procedures, following which early postoperative ambulation was carried out. In an attempt to discover any advantages accruing from this method a control series was carefully studied. This control series consisted of 221 consecutive major operations done from January 1944 to January 1945 by the same surgeon whose only variation in procedure after January 1, 1945 consisted in getting the patient up early. The equivalence of factors renders these two series ideal for comparison.

The 1944 group will hereafter be referred to as group I, and the early ambulation group as group II. In both groups postoperative care was well controlled, and 97 per cent of the

patients were followed carefully for periods ranging from 9 to 21 months.

PROCEDURE OF EARLY AMBULATION

Our present method consists in getting patients up 24 hours after operation irrespective of the type of operation. The patient, having a tight binder applied, is elevated to a high Fowler's position and his legs are swung over the side of the bed. He is gently supported to the standing position and assisted to a chair a few steps away where he sits for a period of 15 to 30 minutes. On the second postoperative day this procedure is carried out twice. From then on the time out of bed and the length of the walks are progressively increased. By the fifth to seventh day the patient is walking to the bathroom himself. Sutures are removed on the 5th or 6th day and stay sutures, if any on the 8th day, unless there is some contraindication. Patients having undergone appendectomies and thyroidectomies are sent home by the 5th to 7th day while all others are usually home 7 to 10 days after operation.

Apart from exceptional cases no patient is allowed to be catheterized. If there is difficulty in urination and defecation the patient is allowed up as often as is necessary even on the day of operation.

The rest of the postoperative care needs no detailed discussion here. Careful observations of the pulse and blood pressure, and routine rebreathing and postoperative exercises are carried out while the patient remains in bed. He is urged to cough even though the act may cause discomfort. Fluid and electrolyte balance is well controlled.

A summary of the data on all 487 cases of both groups is presented in Table I. In evaluating the results of this study both averages and medians are calculated. Because a few values fall far outside the normal distribution curve thus distorting average values, standard deviation from the median is used throughout.

From the Department of Surgery of New York Hospital, New York, New York.

D. Lin has previously been listed in the literature as Dr. Lin-Yuen.

TABLE I.—SUMMARY OF CLINICAL DATA ON 487 MAJOR OPERATIONS

	Average entire series 487 cases	Group I. Late ambulation 21 cases		Group II. Early ambulation 266 cases	
		Average	Median \pm σ	Average	Median \pm σ
Average age of patients	43.4	44.6	46 \pm 6.5	4.9	47 \pm 6.4
Maximum postoperative rise in temperature	-4 C	-4 C	4 \pm 6.7 C	3 C	4 \pm 6.3 C
Postoperative day for maximum temperature rise	4	4	\pm 6.9	3	\pm 6.4
Postoperative day for return of temperature to normal	4.9	6	4 \pm 5.9	4.6	4 \pm 6.8
Postoperative day for ambulation	4.3	9.3	\pm 6.8	3	\pm 6.3
Postoperative day for discharge	5.3	5.4	13 \pm 6.0		\pm 6.7
Complications	8 (3.7%)	8 (3.8%)*		(3.3%)*	
Deaths	20 (4.1%)	(3%)		(1.7%)	

*Standard error of the difference 1.5% actual difference 4.5%

Referring to Table I one finds the median age of group I is 46 \pm 6.5 years while that of group II 47 \pm 6.4 years. The 2 groups studied are thus similar in age.

In like manner it is shown that the figures for maximum postoperative rise in temperature postoperative day for maximum rise in temperature and postoperative day for return of temperature to normal are statistically the same in both groups.

Now in examining the median day for ambulation it is 10 \pm 6.8 days for group I and

σ = Standard deviation of

2 \pm 6.3 days for group II. The difference in the two groups might not seem statistically significant. However reference to Figure 1 shows that group II does not form the normal distribution curve but half of such a curve the peak being along the 1st postoperative day. With group I the peak of the distribution curve is along the 10th postoperative day. Considering this skew the difference in the 2

5		Ventral incisional hernia with fecal fistula	Ventral hernioplasty	Wound infection	7	Resolved

Fig. 2. Group I is indicated by blank area, group II by black area.

groups is greater than could occur by chance, and bears out the claim of early rising for group II.

The median day for discharge for group I was 13th postoperative day ± 8.9 days, that of group II the 11th day ± 8.7 days. This difference could have occurred by chance, but Figure 2 shows the trend towards earlier discharge for group II. The peaks of the curves show a difference of 4 days in day of discharge.

In group I there were 18 complications or 8.5 per cent. and in group II, 10 complications or 3.8 per cent. The standard error of the difference is 2.3 while the actual difference was 4.7 per cent. This difference could have occurred only 1 in 20 times on the basis of chance, and is, therefore significant.

TYPES OF OPERATIONS

Table II indicates the types of operations performed with the number of each. All these cases were done under a combined anesthesia of avertin gas-oxygen-ether.

Hernia. In the repair of all hernias in gural femoral ventral or lumbar, an all silk technique is employed. The wound edges are blocked off with towels as soon as the skin incision is made so as to prevent contamination. The Halsted type of repair is used in both direct and indirect inguinal hernias. Both sides of a bilateral hernia are repaired at one sitting.

Biliary surgery. In cases of biliary tract surgery the approach is through a right paracostal or Kocher type of incision. The wounds are closed with chromic catgut for peritoneum and fascia, with interrupted silk for the skin, and

silver wire as stay sutures. Drainage is maintained for 48 hours.

Laparotomies. Gynecological repairs, thyroidectomies, radical mastectomies complete the list.

As indicated in Table II there were 63 operations for malignant conditions, 34 of which occurred in group II.

Early postoperative complications. Tables III and IIIA reveal not a single case of dehiscence or evisceration either in group I or group II. While wound infections numbered 3 in each group, none of these was among the 179 hernioplasties. There were 4 cases of thrombophlebitis in group I and none among the early ambulation group. Pulmonary complications were 8 in group I as compared to 3 in group II. Coronary occlusion occurred once in each group. Renal complications were more prevalent in group II. One was an exacerbation of pre-existing chronic nephritis after her

neoplasia the other was a temporary renal failure after gastroenterostomy.

Deaths. There were 10 postoperative deaths in each group. Tables IV and IVA give a detailed account and summary report of these deaths. It will be noted that 6 patients in group I and 7 in group II died before getting out of bed. In no case can it be shown that early rising would have prevented death. In all 20 cases of both groups 3 patients died from operative shock, 3 from cardiac failure, 2 from pulmonary congestion, 1 from embolism, 6 from carcinomatous and 1 from cerebral hemorrhage. Thus 50 per cent of the

deaths can be classified as cardiovascular deaths.

FOLLOW UP

Of the 487 cases done 467 patients were discharged alive. There were 17 cases (or 3.7%) that could not be followed. The remaining patients were examined and data carefully recorded. Follow up visits were slated for every 3 to 6 months. Table I shows in detail the follow up record—it is evident that 417 out of 450 patients (or 92.7%) had a follow-up of 6 months or more, and 289 (or 64.2%) had a follow up of 9 months or more.

Keloid formation			4
Late staph. abscess			3
Tenderness in scar			

*20 deaths, and 7 cases (or 3.7%) with no follow-up.

†Small herniations at site of the drain.

‡Preoperative diagnosis: recurrent incisional hernia.

Though a minimum period of 1 year should constitute a fair follow up for herniation to form or reform we believe that most hernias occur or recur within the first 6 months after operation. It will be noted that in group II all hernioplasties were ambulated in the first 24 hours. This group included 4 unilateral recurrent inguinals 3 one sided recurrences in bilateral inguinals 1 recurrent femoral and 1 recurrent ventral. In follow up there was only 1 recurrence in a previously recurrent inguinal hernia as contrasted with 2 recurrences in group I.

Also 4 cases of incisional hernia in group I and 2 small herniations in group II were present at the site of drains.

There were no significant differences in the cosmetic and functional results of the two groups.

EVALUATION OF EARLY AMBULATION

Physiologically early ambulation appears to be sound. Leithauer (5) showed that prolonged recumbency reduces the vital capacity of the lungs, due to reflex inhibition of the diaphragm following abdominal procedures. Churchill and McNeil have expanded upon this point. Standing patients on their feet helps pull down the diaphragm giving better aeration to the lungs. Deep breathing and forced coughing rid the bronchioles of mucous plugs.

Dock believes that the bed pressure on partially filled vessels may cause endothelial changes that give rise to phlebothrombosis with extension from peripheral radicals to

deeper vessels of the pelvis with possible dislodgement of fatal emboli.

Early exercise promotes better circulation and must increase the blood supply to all parts of the operative site. The muscles do not atrophy from prolonged stay in bed and the patient preserves his muscular tone and development.

From the patient's standpoint then his feeling of well being is restored earlier. He does not feel he has been an invalid. He is happy not to have been catheterized and not to have had to use the bedpan. He may have been fearful at the prospect of early rising so soon after operation but became confident after the first trial. Many look back on the idea of early ambulation with approval.

One patient with repair of a double hernia decided that since he was discharged early he could return to work. At the end of 2 weeks he was doing his regular job which included lifting 60 to 70 pounds many times a day. He suddenly realized that he would be ineligible for compensation if he continued so after 3 weeks of heavy labor he stopped work. No ill effects were demonstrable in this patient at subsequent follow up which has covered a period of 1 year.

With the great shortage in hospital beds today the reduction by even 4 or 5 days of hospitalization for each patient is a tremendous

factor in solving this shortage. There is more rapid turnover in cases, which is of interest to the resident staff. The acute shortage of nursing personnel has been alleviated somewhat by early mobilization of patients who are able to take care of themselves early in their convalescence. In the case of those who do not possess hospital insurance the economic advantage of a shortened hospital stay is quite obvious.

SUMMARY

1. Two groups of cases are reported: group I, a control group of 221 consecutive major operations done in 1944 on patients, who were ambulated late; group II, a series of 266 consecutive major operations done by the same surgeon in 1945 on patients who were mobilized 24 hours after operation.

2. There was no significant difference in the postoperative temperature rise nor in the time required for remission of fever.

3. The peak of the ambulation curve for group II was along postoperative day 1 and for group I postoperative day 10.

4. Patients in the early ambulation group are discharged some 4 days earlier than those of the late group.

5. There were 18 complications (8.5%) in group I and 10 complications (3.8%) in group II. The difference is statistically significant.

6. There were 8 pulmonary complications in group I and 3 in group II.

7. There were 5 cardiovascular complications in group I and 1 in group II. No case of thrombophlebitis occurred in the early ambulation group.

8. Not a single case of delirium occurred in either group, although in group II, debilitated patients were subjected to the same early rising routine as the more robust.

9. No significant difference was present in the causes of deaths in either group.

10. There were 97.3 per cent of cases with follow up of which 92.7 per cent were followed from 9 to 21 months.

11. There were 4 cases of incisional hernia in 205 patients in group I or 1.9 per cent; instances in 245 patients in group II or 0.8 per cent. There were 2 cases of recurrences of inguinal hernia in group I and 1 case in group II.

12. The physiological, psychological, and economic advantages of early ambulation are considered.

CONCLUSION

On the basis of this study of 487 unselected, consecutive major surgical cases, early ambulation after operation seems to have no ill effects on the patient. On the other hand, early and late complications are visibly lessened in the early rising group.

LUNG MOBILIZATION

Its Indications in the Management of the "Captive Lung"

HIRAM T. LANGSTON, M.D., F.A.C.S., Chicago, Illinois

THE extensive collective experience which surgeons had as a result of the recent war made possible many advances in traumatic surgery. Above and beyond the general advances made in such fields as chemotherapy or blood replacement, spectacular achievements can be pointed out in specialized practices. In thoracic surgery the light shed on reflex changes incident to chest trauma (1, 2, 3), the bold application of decortication or lung mobilization in organizing hemothorax and hemothoracic empyema may be pointed out among others as achievements of high order in this specialized field (3, 6, 8, 11, 12).

The application to civilian practice of lessons learned from military experience is not always easy and certainly thoracic trauma during peace time is not very common but to stop by simply saying that decortication is indicated in organizing hemothorax would be to miss a much more fundamental principle for which lung mobilization was actually used and possibly to exclude from the surgeon's repertoire a useful approach to problems of chest disease. It seems justifiable therefore to consider the maneuver of lung mobilization at thoracotomy in light of its basic indication.

When critically surveyed decortication or lung mobilization was used in military surgery to provide for the expansion and consequent filling of the hemithorax by useful lung. In organizing hemothorax this was accomplished by removing the coat or 'peel' of organizing fibrin which closely invested the visceral pleura and by this mechanical means effectively prevented any increase in pulmonary volume. The applicability of this basic principle to civilian type surgery seems to justify elaboration.

The total number of factors which may influence or to some extent control pulmonary

re-expansion after collapse is in all probability great. However from a practical viewpoint it is believed that they may be subjected to reasonable classification (4). If considered in the abstract, this problem is very complicated but basically involves an increase in volume of the collapsed lung. To accomplish this three circumstances must obtain: (1) Some substance (air) must enter the lung to provide this bulk; (2) the lung itself must be capable of expansion; and (3) the remaining content of the hemithorax (that content which made up the difference between the volume of the collapsed lung and the volume of the hemithorax) must suffer a decrease in volume corresponding to the first proposition above.

This set of circumstances is applicable in the most commonly seen problem of pulmonary re-expansion, namely massive collapse. In atelectasis relief of the bronchial obstruction by permitting the ingress of air satisfies the first proposition; the lung is usually intrinsically capable of expansion, fulfilling the second proposition; and the remaining pleural content is correspondingly displaceable since it is made up mainly of a shifted mediastinum and elevated hemidiaphragm. A situation easier to understand than the example of atelectasis is of course the common and pertinent one of failure of postthoracotomy re-expansion of the lung or postlobectomy re-expansion of the remaining lobe or lobes. Therefore, in attempting to arrive at a more practical consideration of the problem and avoid a tedious discussion of theoretical variants, the following presentation makes the basic premise that the chest wall is functionally intact.

Putting the three basic requirements for pulmonary re-expansion into other words permits the elaboration of the following scheme of influential factors:

1. Bronchial

Defects of the large or segmental branches
Defects of the smaller branches

From the Department of Surgery, Northwestern University Medical School, Chicago.

- II Pulmonary
 - Defects of the alveoli
 - Defects of the interstitial tissues
 - Defects of combined alveolar and interstitial types
- III Pleural. The presence within the pleural space of
 - Air
 - 1 Simple mantle without tension
 - 2 Due to a bronchopleural fistula
 - a. Nonvalvular defect without tension pneumothorax
 - b. Valvular leak with tension pneumothorax
 - Fluid serous sanguineous purulent etc.
 - Fibrin
 - Pleural investments or distorting pleural symphyses

The bronchial factors are rather obvious and can be brought under the general term of obstruction. Such obstruction may be due to retained secretions, or in postlobectomy lobar collapse, to edema spreading from an adjacent line of bronchial resection or even to distortion of the bronchus, etc. (5-7-10)

The defects of the smaller ramifications of the bronchial tree would also include retained secretions. Their presence in a sufficiently wide area of the bronchial tree to be of significance in a postthoracotomy patient could for example, result from the application of positive pressure by the anesthetist without adequate prior tracheobronchial toilette. The possibility that tracheobronchial secretions may actually be driven beyond easy reach by poorly managed positive pressure anesthesia is probably not as widely appreciated as it should be.

The pulmonary factors are usually not encountered in a recently thoracotomized patient but do assume importance in long-standing collapse. Edema exudate or blood may of course fill the alveoli rendering them airless and heavy and thereby prevent adequate expansion (11). Extensive retention of lipiodol may possibly be operative in this manner (5). Because of prior disease or long-standing collapse under a progressive type of pleural exudate the interstitial tissues may be the site of such extensive fibrosis that they will not permit adequate increases in pulmonary volume (12).

The pleural factors may, of course be varied and many. They all embody however the

idea of preventing increases in pulmonary volume because of their presence and if they are the only factors preventing lung expansion, a direct approach for their correction is not only possible but is usually necessary. Just as bronchoscopy may disclose or remove the bronchial factor so thoracentesis can demonstrate and correct most of the pleural factors.

The presence of a simple mantle of air provides a self-correcting situation because it can be expected to undergo absorption and disappear eventually. A tension pneumothorax, however, is a much less benign situation, but again manageable by well established routine. Certainly a lung cannot expand under an undecompressed tension pneumothorax, but the recognition of this condition poses no unusual problem. The presence of a nonvalvular leak of small size may not prevent eventual lung expansion but will certainly delay it. A tension pneumothorax provides for progressive lung collapse, whereas the nonvalvular leak not only maintains an adverse pleural factor (pneumothorax) but also interferes materially with the efficiency of pulmonary inflation. Even though neutralization of these situations may tax the surgeon's ingenuity to the utmost, such discussion is not within the scope of this paper.

Pleural fluid as a factor probably needs no comment except to point out its significance in being usually associated with some more fundamental pathologic process.

The presence of fibrin or pleural investment or deforming pleural symphyses strikes a new note in this problem in direct application of the lessons learned in the recent war. The presence of fibrin prevents expansion by its bulk, but if it be removed the remaining and probably constantly concomitant pleural coat of organized fibrin will still prevent or greatly delay expansion. This situation provides a lung that may be entirely capable of expanding except for the fact that it is retained or held captive mechanically in the collapsed position by a restricting fibrous investment. That minor degrees of this process in the form of distorting pleural symphyses may greatly delay expansion has previously been pointed out (9).

Returning now to review this problem in its entirety bronchoscopy, clinical evaluation and thoracentesis provide the essential diagnostic as well as therapeutic approaches. Bronchoscopy should reveal and/or eliminate the bronchial factor. Clinical evaluation at least, should reasonably disclose and indicate treatment for a pulmonary factor. Obviously such appraisal may of necessity amount to an extensive investigation but in the recently thoracotomized patient the status of the lung should be well known, either because of the preoperative studies or the information obtained at operation or both. Thoracentesis should permit accurate recognition of most of the possible pleural factors. can correct many of them and should be able to point to proper treatment in all.

A pleural factor not reducible by thoracentesis such as fibrin or the lung which refuses to expand after removal or neutralization of the pleural factor requires thoracotomy for its correction subservient of course to the previously mentioned diagnostic steps by which important and basic etiologic considerations should be elucidated.

It is believed, therefore, that if a patent and normal bronchial tree is present in a lung that

Fig. 1. Case 1. Admission roentgenogram, indicating the extensive left hydropneumothorax which totally covers the lung and greatly displaces the mediastinum toward the right.

has no intrinsic cause for nonexpansibility yet fails to expand after elimination or neutralization of the pleural factor the diagnosis of a captive lung or a lung that is retained mechanically in this state of collapse can be made with reasonable certainty and thoracotomy for its

Fig. 2. Case 1. a, Posteroanterior roentgenogram taken before thoracotomy and decortication. Although the mediastinum has returned to a more normal position, the lung has failed to re-expand significantly, particularly in its apical portion. The evidence of basal loculation is noted and what apparent filling of the hemithorax has occurred is actually due to continued and severe contraction of the chest wall. b, Lateral roentgenogram of same date as a.

Fig. 3. Case 1. Bedside roentgenogram taken 45 hours after decartication. The basal fluid level is the result of accidental occlusion of the posterior intercostal drain. The lung is, however, virtually completely re-expanded.

correction is justified if such prompt re-expansion is not contraindicated on etiologic grounds.

The following case reports will serve as illustrations of the principles which have been discussed.

Fig. 5. Case 2. Bronchogram illustrating the extent of bronchiectasis. Additional projections and more complete left-sided filling are used to clearly indicate the extent of involvement of the upper lobe.

Fig. 4. Case 1. Roentgenogram showing final result. A 1 tercostal incision, as used without rib resection. The left hemithorax is approaching normal volume and good functional result was obtained even though lateral "tenting" of the hemidiaphragm is present.

CASE 1. G. R. B. male white aged 30 years, is referred for treatment with the following history. On November 19, 1945 while sitting at the breakfast table he developed a sudden sharp pain in the epigastrium, accompanied by hoarseness of breath. He was treated by bedrest and given symptomatic care for 4 or 5 days when he was hospitalized. A fluctuation in the left chest was recognized and 200 cubic centimeters of air and 200 cubic centimeters of bloody fluid were aspirated providing some relief. Because there had been no noticeable improvement in the condition of the chest even though symptoms had abated, he was referred for definitive care on December 29, 1945.

The admission x ray film revealed an extensive hydropneumothorax on the left (Fig. 1). This was decompressed and the pleura emptied, requiring partial air replacement for control of negative pressure symptoms. The fluid was thin, bloody and sterile. No acid fast bacilli were found in the pleural fluid nor in the gastric content. There was no sputum and no history of lung disease. Bronchoscopic examination revealed a dry and patent bronchial tree. The pleura was repeatedly aspirated removing air and any re-accumulating fluid (which was negligible in amount) but no indication of pulmonary re-expansion could be detected. Careful manometric readings of intrapleural pressures gave no indication of a bronchopleural fistula. Instead, contracture of the left chest became more pronounced. On the basis of these findings the lung was considered to be "captive" probably on the basis of an investing pleural "coat" or binding pleural adhesions (Fig. 2a and b).

On January 28, 1946 a thoracotomy was performed. The lung was found to be in a state of virtually complete collapse and covered by a "peel" typical of or

Fig. 6 Case 2. Bedside roentgenogram of July 27, 1946. The collapsed lobe is clearly seen, as is the mediastinal shift and elevation of the left hemidiaphragm. A fluid level is present as well as the suggestion of a mass partially filling the pleural space.

Fig. 7 Case 2. Bedside roentgenogram of August 3, 1946. There has apparently been some readjustment of the mediastinum toward its normal position but no increase in volume of the remaining lung. Fluid and the probable intra-pleural mass persist despite all efforts at emptying the pleura.

ganizing hemothorax some 2 millimeters in thickness. Decortication was surprisingly easy and lung expansion full and prompt. His postoperative course was uneventful and he was discharged in a state of full functional capacity (Figs 3 and 4). The site of leak from the lung which had resulted in the spontaneous hemopneumothorax was not recognized at the time of operation.

CASE 2. R M. male white, aged 21 years was admitted on June 12, 1946 for treatment of bronchiectasis for which he had received a medical discharge from military service. A productive cough had been present since 1940, which symptom had appeared following an attack of influenza. Two bouts of hemorrhage had been experienced.

After appropriate study and a suitable period of preoperative preparation (Fig. 5) the left lower lobe and the lingular portion of the upper lobe were resected by individual ligation technique without difficulty on July 25, 1946. Anterior and posterior intercostal drains connected to water seals were employed. The remaining lung inflated in an entirely satisfactory manner prior to closure. The postoperative reaction was minimal and no concern over his welfare was felt until the bedside roentgenogram on July 27, 1946 (Fig. 6) was seen despite the unfortunate emptying of one of the water seals shortly after operation.

Renewed efforts in order to insure adequate evacuation of the pleura were made which included aspiration of the chest, breathing exercises, forced coughing and continuous pleural decompression. Suction on the intercostal catheter was poorly tolerated be-

cause it soon produced acute thoracic discomfort. Sputum was being adequately raised. The fluid obtained from the left pleural space was sterile on culture but was viscid and serofibrinous in character. At bronchoscopy, the bronchial tree was relatively dry, the upper lobe orifice was clearly patent, there being no rotation or encroachment by edema to any significant degree. A curved vertebrated suction tip could be easily introduced into the upper lobe bronchus. No secretions were obtained by this maneuver. Throughout this entire time the patient's clinical course was very favorable despite persistent collapse of the remaining lung (Fig. 7). Thus since the bronchial factor was presumably eliminated there was no known or demonstrable pulmonary factor, no bronchopleural fistula could be demonstrated and evacuation of the pleural content which was as complete as could be tolerated by the patient (checked by fluoroscopy) failed totally in promoting re-expansion of this lobe, the diagnosis of a captive lung or a lung retained in the collapsed position probably by fibrin seemed justified.

Accordingly on August 6, 1946 the thoracotomy wound was reopened. The pleural space was found to contain some residual fluid but a large mass of fibrin comprised most of the volume therein and closely invested the lung which lay totally collapsed in the gutter posteriorly. After manual removal of this fibrin mass a peripleural coat of organized fibrin was recognized and decortication undertaken and carried out fairly completely although its age (only 12 days) rendered it thin enough that some shredding occurred. This procedure was carried out over the

Fig 8. Case . Bedside roentgenogram 48 hours following second thoracotomy. Immediate and very gratifying re-expansion has occurred.

Fig 9. Case . Immediate final result. The basal opacity is due to residuals of the small complicating empyema which required drainage.

entire lung surface including the line of the lingular resection. At the points where this coat came near the stumps of the hilar elements however such intimate dissection seemed more hazardous than was justified even though no doubt complete freeing of the lung base in this area would have been advantageous. Nevertheless this decortication permitted the lung to expand very adequately on increasing intratracheal pressure which was not at all possible before. The chest was closed and the pleura was again drained by an anterior and posterior catheter. The postoperative result was very gratifying (Fig 8) there being prompt expansion of the lobe and progressive filling of the beneath rax by lung. A small basal empyema did develop requiring drainage through the posterior catheter opening.

The patient was discharged with the empyema healed and with only minimal basal residuals visible by roentgenogram (Fig 9).

Neither of these cases would permit the diagnosis of massive organizing hemothorax or fibrinorhax as the usual traumatic case was envisioned (9). In Case 1 the pleural content was aspirable readily and easily the air replacement being necessary for control of negative pressure symptoms only. Case 2 did reveal a residual intrapleural mass by x ray examination in addition to the shadow cast in the roentgenogram by the collapsed upper lobe, but again the bulk of pleural content was aspirable in satisfactory fashion.

Nevertheless these cases illustrate the points in diagnosis required to establish the fact that the lung could not expand because of a retaining pleural factor.

1. There was no evidence of bronchial obstruction.
2. There was no known intrapulmonary factor in Case 2 and no reasonable probability of such in Case 1.
3. The demonstrable pleural factor in Case 1 could be neutralized by aspiration and at least partially neutralized in Case 2 by means of the same method. No evidence of bronchopleural fistula could be adduced in either case.
4. Both patients had a pleural factor reasonably capable of producing a retaining peripleural coat—blood in Case 1 and serofibrous pleural fluid in Case 2.

SUMMARY

1. The factors governing lung re-expansion after collapse are reviewed and a working classification of them is given.
2. The essential points in establishing the diagnosis of a lung that is retained in the collapsed state by pathological peripleural investments are discussed and the relation of this process to organizing hemothorax or fi-

LANGSTON LUNG MOBILIZATION

brinnothorax as seen in thoracic wounds of violence is shown

3 Two cases are reported in which these principles in diagnosis and their effective treatment by thoracotomy and decortication are illustrated

A NEW ESCHAR TECHNIQUE FOR LOCAL TREATMENT OF BURNS

CLYDE H. CHASE, M.D., D.Sc., Detroit, Michigan

THE principal objectives in the treatment of burns have been well summarized by Allen and Koch and by Green and it has been pointed out by them that the primary aim is to save life, and to restore the function and the appearance of the injured individual to as near normal as possible.

Since this article will deal only with the local therapy of the burned area, all of the objectives in the treatment of thermal injuries will not be listed but only those which are directly related to the wound. These objectives are listed below and they should be attained when feasible, by the most efficient the simplest, and least complicated method

1. The prevention or minimizing of shock—a reduction in the plasma volume during the period of shock is prevented by minimizing the internal and external loss of fluid, salts and protein.
2. The relief of pain both the immediate pain and subsequent pain due to dressings.
3. The prevention or minimizing of infection (early and late)
4. The use of a local form of therapy which will not interfere with the patient's recovery either because of undesirable systemic or local effects.
5. The reduction of the external and internal protein and salt loss to a minimum during the convalescent period
6. The induction of healing as promptly as possible or in the case of a third degree burn the preparation of the burned area for grafting at the earliest possible date.
7. The provision of rest for the injured part.
8. The provision of a form of treatment in which the progress of the wound can be expeditiously observed without fear of contamination.

During the past 10 years two methods of treatment have been widely used, namely that of applying a chemical coagulant which forms an eschar (3 5 14) and the method employing petrolatum or an ointment on the burned surface with an overlying pressure dressing (4)

In a recent article, Bettman (6) presented his results on the treatment of over 700 patients with 5 per cent tannic acid and 10 per cent silver nitrate. In his series, the mortality rate was 3.1 per cent and he pointed out that several patients with very severe burns survived (over 70 per cent of the body surface involved). The cause of death in this series could in no instance be attributed to the toxic properties of tannic acid. In a group of patients which the authors regarded as being too small to permit any definite conclusions, Saltonstall, Walker Rhoads and Lee had a lower mortality rate in those treated by the tannic acid method than with pressure dressings. However they also showed by liver function tests that the tannic acid and other chemical eschar methods produced some impairment of liver function which was not evident in the patients treated by the vaseline pressure dressing method. Experimentally these findings have also been corroborated by Clark and Rossiter.

Rae and Wilkinson pointed out that the extent and likelihood of liver damage is much greater when tannic acid jelly is employed than when the tannic acid silver nitrate method is used. The report by McClure, Lam and Romence substantiates this view. The latter group as well as Allen and Koch, showed a significant decrease in the mortality rate when the tannic acid method was abandoned for the nonadherent pressure dressings.

It is not the purpose of this paper to discuss the relative merits of these two forms of therapy but to point out that they are not entirely adequate, at least by a theoretical analysis, and to present a new form of treatment which more completely fulfills the objectives of the local burn therapy here outlined.

METHODS AND RESULTS

On the theory that animal tissue might provide a suitable and effective substance which

would form a more physiological eschar than tannic acid or the other tanning agents do numerous extracts of various tissues were tried. An extract made from beef aorta reacted in the desired way. The protein thus obtained can be used in saline or in an ointment containing glycerine and diglycol stearate (it can also be made with 5 per cent sulfathiazole, or by adding one hundred thousand units of penicillin to 20 to 30 grams of ointment). The purified extract of the beef aorta is a protein, but is apparently free of albumin proteoses and peptones. This extract in the treatment of burns has been under experimental and clinical study for several years and has been used in various vehicles (saline solution or paste containing several different antiseptics). I have employed this treatment in over 500 ambulatory cases and it has also been used in an additional group of over 250 patients with more serious burns by Weller and Zyla.

Judging from these clinical observations and studies on animals, the protein extract from the beef aorta reacts in the following manner:

a. It forms a dry slightly flexible eschar over denuded surfaces of the skin and if necessary can be softened by water or saline solution. This property permits it to be removed very easily without damage to the underlying tissue. Other workers (1, 20, 31, 32) have described similar findings in employing plasma or fractions of plasma for the local treatment of burned areas.

b. The extract in saline solution or made up in the form of a salve containing sulfathiazole sodium 2 hydroxydiphenyl glycerol and diglycol stearate does not injure tissue (7, 10) and shows no evidence of retarding tissue growth. Figure 1 shows a histopathological section taken 6 hours after an application of the protein aortic-extract in an ointment containing 5 per cent sulfathiazole following the removal of the epidermis from the skin of a pig by a dermatome. This section

This extract is prepared by grinding the beef aorta and then washing it to remove the excess blood. The washed material is then extracted with one-tenth normal sodium hydroxide solution for one hour and filtered. The filtrate is reduced to a paste approximately 4. by the addition of dilute hydrochloric acid and the precipitate thus formed is then recovered by filtration. This product then may be redissolved in a physiologic solution of sodium chloride and used as a spray or it can be worked into a paste or ointment.

showed very little reaction in comparison to like sections which were taken after the employment of tannic acid or a vaseline pressure dressing (7, 9).

c. This material can be applied locally by spray or paste or incorporated into fine mesh gauze and a dressing employed (with or without pressure). Since the eschar separates readily when infection or epithelialization occurs, its removal presents no problem.

d. The protein extract with or without added antiseptics adheres to the burned skin surface and remains dry until the wound has healed or the slough begins to liquefy. The same observations have been made by others using a similar method (1, 31).

e. Weeping surfaces show a prompt decrease in the loss of fluid after application of the protein extract, which also occurs when other types of eschars are used (18, 26, 32).

f. It rapidly relieves pain when applied to first, second or third degree burns.

g. If the bandaging method is employed, one application is sufficient, and at any time within a few hours, inspection of the area may be carried out by raising the outer protective dressing. No discomfort is experienced and the lesion is protected from air borne infection because of the eschar. Infected areas can be easily recognized as the eschar liquefies and disintegrates (similar properties have been noted (1, 10, 20, 31, 32) when fractions of human plasma have been used).

h. Gauze impregnated with the ointment will form an eschar which is slightly flexible and capable of withstanding considerable trauma and pressure.

The eschar formed on denuded surfaces with this form of treatment approaches in appearance that which normally occurs when the skin is injured mechanically (32).

If the eschar is broken tissue fluid exudes which promptly closes the opening by forming a scab thus sealing off the wound.

In third degree burns it has been noted that the slough separates at least as early as when other forms of therapy are employed. Since early inspection of the wound is possible, without pain or fear of contamination, skin grafting can be accomplished at the earliest possible date. The extract will not cause any irrita-

tion nor will it firmly adhere to the normal epidermis, hence the outline of the injury is depicted by the adherent protein. When the eschar desquamates from a second degree burned area, the tissue beneath is soft. In a deeper burn as the necrotic tissue separates, the underlying granulations are clean firm and red (Edema of the denuded area is absent or minimum unless infection occurs.) Small areas of infection which may be present in fairly extensive burns can usually be recognized quite early. They can be treated by sponging the area with saline or any water soluble antiseptic and after it has been well cleaned the region can be again covered with the protein extract. The properties of this extract have been tested to determine if it produces any allergic reactions. (The details of these tests will be published later. However no undesirable results have been encountered clinically or experimentally.)

The aorta extract in the form of an ointment or as a solution should be applied to the burned area preferably after it has been thoroughly cleansed.

If the blisters are broken but the wound is clean the injured skin can be pulled over the denuded area. Small unbroken blisters are left intact and large blisters are drained. A method of cleansing the wound by spraying using a standard seltzer bottle to which is attached a rubber tube carrying a DeVilbiss spray head has been used satisfactorily. The cleansing solution which has been found satisfactory is an antiseptic detergent diluting one part of the detergent to ten parts of sterile water. One carbon dioxide capsule may suffice but two capsules will completely empty the bottle at a more satisfactory pressure. The pH of the antiseptic detergent is on the acid side and works well with the aortic extract. Following the use of the antiseptic detergent the wound is flushed with sterile normal saline. If this is not done the eschar usually is too thick. If the eschar becomes too firm this can be relieved by applying an ointment with an oily base. The ointment or solution containing the extract is then applied and the patient is placed in a heat tent or a box splint may be employed for burns of the extremities in ambulatory patients. When dressings are used

the ointment can be applied directly to the burned area which is then covered with fine mesh gauze or it can be incorporated in the gauze which is placed over the burned area. Several layers of dry gauze are then applied and bandaged.

Other observations concerning the therapeutic possibilities of this protein extract are of interest. When it is applied to the early vesicles of herpes simplex, it adheres to the small vesicles which usually desquamate in about 24 hours, leaving a smooth but erythematous area, which will appear entirely normal after the extract is reapplied and desquamation again occurs. An erythema resulting from sunlight or ultraviolet light will be relieved and the pain alleviated if the protein extract is applied early. The flare and accompanying discomfort resulting from many types of insect bites is also relieved in a few minutes following the application of this material, while on the other hand the vasodilation resulting from histamine hydrochloride shows no response to the application of the protein extract. The aortic tissue extract does not delay or accelerate the coagulation of whole blood. However it does delay coagulation of thoracic lymph.

DISCUSSION

In order that the method just described can be evaluated from a theoretical standpoint it is best compared to other forms of treatment in relation to the objectives outlined.

1 The prevention or minimizing of shock—reducing the external and internal fluid loss. Experimental studies have shown that the eschar method (18 26 32) will prevent the external loss of fluids, electrolytes, and protein and that the nonadherent pressure dressing (8 34 36) will reduce the formation of edema in the injured area, if applied early. However local edema without external loss may occur when tanning agents are used, and a plasma-like fluid may seep from the injured surface for days when pressure dressings are employed. Since an eschar which does not injure tissue can be produced and at the same time a pressure dressing may be employed, the protein extract should be the preferable method.

While pressure dressings may be used cotton or mechanic waste have been found to interfere with the formation of an adequate eschar. Because many of the patients exhibit some edema prior to the time the wound is dressed and since pressure dressings are only effective on the extremities the open method or the closed method employing loose dressings are usually used.

2 The relief of pain—immediate and subsequent pain. Following local treatment with all three methods pain is usually readily relieved but since the removal of a tannic acid eschar or changes of a pressure dressing are often uncomfortable the aorta extract is preferable.

3 The prevention or minimizing of infection—early and late. All three methods if carefully employed should be quite adequate. During the first few weeks however when dressings are changed the danger of introducing air borne bacteria should be less when an eschar is present. While there is some controversy over the desirability of applying the sulfonamides or antibiotics locally many workers (2, 25, 27) feel that such therapy is of some benefit. On the other hand Meleney failed to demonstrate a statistically significant reduction in the incidence of infection in a large group of patients that had local applications of a sulfonamide, when compared to a control group of similar cases. However he does state that it seems likely that the use of the sulfonamides may have minimized the spread of the local infection and therefore reduced the incidence of septicemia and death. Whether bacteria can be inhibited or not by such means is not within the scope of this discussion. It should suffice to say that a bacteriostatic substance can be employed with a nonadherent pressure dressing or with the protein eschar method if desired.

The following points should be kept in mind if the sulfonamides are to be employed: (a) They should not be used to replace careful surgical technique (15). (b) They should not be dusted on an open wound in a powder or crystalline form or used in a water dispersible base (15, 16, 24) but should be employed only where a limited slow absorption of the drug will occur. A 5 per cent suspension of

Fig. 1. A histopathological section taken 6 hours after application of the protein aortic extract. A uniform thickness of epidermis was removed from a young pig. Sections were taken from a control animal and when various other forms of treatment were employed. This section shows little reaction in comparison to like sections treated by other methods (7, 28).

sulfathiazole in aortic tissue ointment applied to 13 per cent of the body surface on rabbits subjected to second degree burns and the surface mechanically denuded showed an average blood level in 6 animals of 1 milligram of free sulfathiazole per 100 cubic centimeters of blood in 2 hours, the same in 6 hours and a trace in 7½ hours. The highest level encountered at any time was under 2 milligrams. Levels indicating that the absorption was too rapid were seen when sodium sulfathiazole was used so this was not employed (10).

Since the pressure dressing method has not yet been sufficiently evaluated disadvantages may still become apparent. In Bettman's (6) cases, infection occurred more frequently when a greasy ointment was applied locally. Experimentally (19) the incidence of Curling's ulcer was found to occur more often in animals treated by the vaseline pressure dressing method (66 per cent) than when tannic acid or other eschar forming substances were employed (6 per cent). However the pressure dressing method is not suited for animal experiments and infection seemed to be the

Fig. 2. Case J57. Age 34 years. Subjected to second degree burns of the back, buttocks, posterior thighs, lower half of abdomen and upper right arm, on January 4, 1943, when he fell in bucket of hot water. Child was treated for shock with saline and plasma 3 hours after the accident. Burned area was douches with saline. The cortic tissue extract ointment was applied to the abdomen, the layer gauze. Patient as placed in heat tent, face down, and the tissue extract ointment was applied to the back, buttocks, thighs, and right arm. Eschar formed in 3 hours. Eschar began falling off the 5th day and all areas are completely healed the 14th day (Courtesy of Dr. C. N. Weller).

major factor in causing the high incidence of Curling's ulcer.

4. The use of a local therapy which has no undesirable systemic or local effects. The nonadherent dressing or the protein eschar

method has no known undesirable systemic or local effects. It has been demonstrated conclusively that tannic acid and other tanning agents will cause some impairment of liver function (35). It has also been pointed out (37) that if a patient is placed in a tub containing tannic acid or if the jelly is employed (39) the danger of liver necrosis is a real hazard. Clinical studies (9, 21) and experimental animal work (28) have shown that healing is impaired and some normal tissue destroyed when tannic acid or other chemical coagulants are used.

5. The reduction of the external and internal protein loss. It has been shown (12, 22) that the amount of protein or nitrogen lost externally from a wound may be quite large, and Cuthbertson has again recently emphasized the importance of this loss. For the reasons enumerated in the first part of the discussion the protein eschar method is preferable. Even when the open method is used the edema does not seem to be as great as that observed with other methods. Some studies have been made with the use of this type of

Fig. 3. Case J60. Suffered second degree burns of face, neck, scalp, and ear, January 4, 1943. Wounded area was douches with normal saline. 3/4 hours after being burned with hot gravy. The cortic tissue extract ointment was applied. The eschar was formed in 3 hours. Tissue extract was applied to the chest for the second time January 5, 1943. Lesion was completely healed January 13, 1943. (Courtesy of Dr. Weller).

therapy and although not complete they seem to indicate contrary to what other observers (12-22) have found when pressure dressings are employed that the external nitrogen loss is negligible from the area of a second degree burn.

6 The induction of healing as promptly as possible and the preparation of the third degree areas for grafting at the earliest possible date.

From a study of a limited number of cases it appears that the healing and grafting processes are possibly accelerated when the protein eschar method is employed. The experimental and clinical studies by Hoffman and Dingwall and the observations of others (31-32) help corroborate this impression. Therefore, it is believed that this method can be considered at least as efficient as the nonadherent pressure dressing method.

7 The providing of rest for the injured part. This could be accomplished by any of the three methods of therapy but it should be easier by the protein eschar with dressings or splints or with the nonadherent pressure dressing method.

8 The providing of a form of treatment in which the progress of the wound can be expeditiously observed without fear of contamination.

Experience with the protein extract method indicated that this form of local therapy is superior to the two commonly employed methods. When the vaseline pressure dressings have been used patients with fever and without wound infection have frequently had the dressings removed unnecessarily for examination of the burned area. On other occasions with the pressure dressing or tannic acid eschar methods the infection has spread rapidly and extensively before the wound was observed.

If the protein eschar method is employed the open treatment can be used or if dressings are applied they can be easily removed and the burned area can be inspected frequently. If a small area under the eschar becomes infected it softens or liquefies thus indicating the presence of infection. It can then be cared for early and further spread prevented.

SUMMARY

1 A new method for the local treatment of burns has been described.

2 This method has all of the advantages offered by the other available methods and no known disadvantages.

3 It has been effectively employed in over 500 ambulatory burned patients. Since these patients were not extensively burned no definite conclusions can be drawn regarding the results of this treatment on the mortality rate but there is reason to believe that it should be at least as effective as the other available forms of local therapy.

PULMONARY EMBOLISM BY AMNIOTIC FLUID

Report of 3 Cases with a New Diagnostic Procedure

PAUL GROSS M.D. and EDWARD J. BENZ, M.D. Pittsburgh, Pennsylvania

IN 1941 Steiner and Lushbaugh (5) described maternal pulmonary embolism by amniotic fluid thereby adding another entity to the pathology of parturition. DeLee maintained that "The number of possibilities this discovery suggests is uncountable at present and be called it an exquisitely interesting discovery. In most of the cases thus far reported this catastrophe occurs during the course of labor or the immediate puerperium and is characterized by the appearance of sudden profound shock followed by the death of the mother and frequently of the fetus. Postmortem examination reveals no significant gross finding to explain the cause of death. However the microscopic appearance of the lungs is diagnostic. The sections exhibit a relatively bloodless vascular bed in which many of the vessels are occluded by polymorphonuclear leucocytes and the particulate constituents of amniotic fluid (epithelial squamæ mucin granular débris etc.) A variable degree of pulmonary edema may be associated with this condition.

A total of 10 cases was reported by Steiner and Lushbaugh 8 in 1941 (5) and 2 in 1942 (3). No other report of this disease could be found in the literature. Very recently 1 additional case was described by Burt.¹

In this communication we hope to rekindle interest in this condition with the presentation of 3 new cases and a procedure whereby the diagnosis can either be verified at autopsy or perhaps established when autopsy is impossible.

CASE REPORTS

CASE 1: A 35 year old white woman secundipara was admitted to the obstetrical service (Dr. J. W. Stevenson) in active labor 21 days after the expected date of confinement. She had had one pregnancy 8 years previously which was normal. The past medi-

cal history was not significant. The present pregnancy had been normal. Eleven hours previous to admission bloody vaginal discharge appeared followed in 2 hours by the first labor pains 15 minutes apart. About 9 hours later the membranes ruptured spontaneously. On admission uterine contractions were tetanoid in character occurring at 5 minute intervals and lasting 20 seconds. Rectal examination revealed 3 1/2 centimeters dilatation of the cervix with moderate effacement. The fetus was in the left occipitoanterior position of a vertex presentation and had a heart rate of 130 per minute. No significant abnormalities were found on routine physical examination. The blood pressure was 118/76. Temperature, pulse and respiratory rate were within normal limits. The results of urinalysis and serologic tests were negative.

One hour after admission the patient was given demerol, 100 milligrams and scopolamine, grains 1/150 (0.4 mgm.) hypodermically. One hour and 45 minutes later the cervix was fully dilated and effaced. There was an emesis of undigested food particles at this time. Immediately after being placed upon the delivery table the patient became restless and complained of chilliness. The skin was cold and clammy. This was followed by severe hyperpnea and coma. Within 15 minutes the patient was apneic pulseless and intensely cyanotic. There was conjugate deviation of the eyes to the right. The blood pressure was 30/00. Emergency measures evoked no response and death occurred 40 minutes after the onset of symptoms. A dead, cyanotic fetus was delivered during the last 5 minutes by version and extraction.

The autopsy performed 3 hours after death yielded only nugatory gross findings. However, the blood within the heart and vessels was everywhere fluid. No clots were observed. The left and right lungs weighed 235 and 270 grams respectively. There was a small amount of frothy blood tinged mucus in the left bronchial tree. The uterus was normal for its puerperal state. The placenta was not available for examination. The other organs were grossly normal.

Microscopically the arteries and most of the arterioles of the lungs are occluded by a mixture of polymorphonuclear leucocytes, monocytes, acidophilic granular débris, and basophilic fibrillar material, and contain few or no red blood cells. The leucocytes are frequently arranged in parallel rows as though raked or combed. The endothelial lining of the vessels is normal and no leucocytes are found within the vessel wall or in the perivascular tissue. Epithelial squamæ (Fig. 1) and occasional bits of

From the Pathologic Laboratory of St. Joseph Hospital.
While this paper was in press another case report appeared.
Hemmings, C. T. *Am. J. Obst.*, 1947 55 303-306.

Fig. 1. A bloodless pulmonary artery from Case 1 which contains epithelial squames, mucus, and leucocytes. Hematoxylin and eosin stain. $\times 50$.

Fig. 2. A smaller pulmonary arterial branch from Case 1 which contains leucocytes and granular material but no blood. Hematoxylin and eosin stain. $\times 50$.

bile-stained granular debris are present in a few small vessels. The alveolar spaces are empty except for a few which contain a small amount of fluid. The bronchi are normal.

The liver sections show slight separation of the sinusoidal endothelium from the liver cords by albuminous fluid. Sections of the spleen exhibit severe passive hyperemia. Sections of other organs, including the uterus, show no significant abnormality.

CASE 2. A 4-year-old white woman, *tertipara*, was admitted to the obstetrical service (Dr. J. C. Hughes) 10 days before the expected date of confinement. There were 3 normal pregnancies 20 and 22 years previously. The past medical history was essentially negative.

At 6 months of the present pregnancy the patient was hospitalized because of pernicious vomiting and intermittent uterine contractions. At this time she was poorly nourished, moderately dehydrated, and had lost considerable weight. Physical examination disclosed no abnormality other than a mild dermatitis over the anterior abdominal wall. The results of urinalysis and of serologic tests were negative. A moderate secondary anemia was present. After 6 weeks of supportive therapy and bed rest she was discharged much improved and had no recurrence of vomiting.

The patient was readmitted at term with rhythmic contractions every 30 minutes and some bloody vaginal discharge. The fetus was in a vertex presentation with the head at the pelvic inlet. The cervix was thick and 3 centimeters dilated by rectal exam-

ination. Fetal heart sounds were of good quality in the left lower quadrant. The membranes were unruptured. The uterus appeared excessively enlarged and its contractions were strong. Physical examination revealed no significant abnormality. The blood pressure was 120/70, pulse temperature, and respiratory rate were normal. Urinalysis yielded no abnormal finding.

Because of the extensive uterine distention, an abdominal binder was applied, the membranes were ruptured artificially and about 1 liter of amniotic fluid was drained off. During the following 4 hours little progress was made and 6 pitocin injections were given, minimum and 2 minimum doses, alternating every half hour. This was ineffective and labor advanced slowly during the next 24 hours despite a repetition of the pitocin injections. Thirty-four hours after admission she began to have severe tetanoid contractions and made rapid progress. Ten hours later the cervix was fully dilated and effaced. Fetal heart sounds were of good quality at this time. One hour later the patient was delivered of a still-born male infant by outlet forceps under nitrous oxide-oxygen-ether anesthesia. Immediately following delivery the patient became cyanotic, hyperpneic, and exhibited evidence of severe shock. The placenta was delivered without difficulty. The patient became progressively more cyanotic, clammy, and pulseless and died 65 minutes after the onset of symptoms despite immediate antishock treatment.

Autopsy was performed 23½ hours after death. On opening the abdomen, about 300 cubic centimeters of

Fig. 3. A pulmonary artery from Case 3 which is plugged by masses of leucocytes and granular material. Several epithelial squamulae and some rubeus are also present. Hematoxylin and eosin stain $\times 90$.

Fig. 4. A pulmonary artery from Case 3 which contains a hair shaft (lanugo) in addition to leucocytes as well as a small amount of debris. Hematoxylin and eosin stain $\times 140$.

bloody fluid were encountered. There was diffuse bloody extravasation into the preperitoneal tissues of the anterior abdominal wall below the umbilicus. There was also ecchymosis at the root of the mesentery and the mesenteric attachment of the terminal ileum and appendix, extending laterally to the cecum. This ecchymosis also involved the right broad ligament of the uterus with the corresponding tube and ovary. All these tissues were edematous. The blood within the heart and vessels was everywhere fluid; no clots were observed.¹ The left and right lungs weighed 175 and 210 grams respectively and were grossly normal. The liver was normal except for severe pallor. There was moderate dilatation of the left ureter and the left renal pelvis. The uterus was normal for its puerperal state. The placenta was not available for examination. Other organs were normal.

Microscopically most of the pulmonary arterioles and alveolar capillaries are bloodless and are occluded by polymorphonuclear leucocytes and a small amount of granular debris (Fig. 3). Some of the larger vessels are similarly involved. Mucus as seen in Case 1 is demonstrable in a medium sized artery, but no squamulae are seen. The endothelial lining of the affected vessels is intact and the cells are not swollen. There is no indication of leucocytic migration within or outside of the vessel walls.

The liver cells are swollen and the sinusoids narrowed. The latter contain only occasional red blood cells and present instead, many polymorphonuclear leucocytes and monocytes. An occasional small por-

Blood removed from the right auricle was inoculable. It was placed in refrigerator but unfortunately was not examined until weeks later. After centrifugation, the sediment contained, in addition to the usual red cell layer and leucocytic cream, top stratum of white flocculent material. Although shreds suggestive of mucus are found in smears made of this top layer, identification was not positive and the results were considered equivocal.

tal vein shows similar cellular content together with a small amount of acidophilic, granular debris.

No significant abnormality is noted microscopically in the other organs.

CASE 3. A 35 year old white female quintipara was admitted to the obstetrical service (Dr J J Weber) in active labor 1 month prior to the expected date of confinement. There had been 4 previous full term pregnancies 15, 10, 5 (stillborn) and 3 years previously. The past medical history was essentially negative. The present pregnancy was uneventful and the patient entered labor in an apparently healthy state.

The first labor pains began about 8 hours before admission, occurred at 10 minute intervals, and were accompanied by a slight bloody show. On admission the contractions occurred at 5 minute intervals and lasted 30 seconds. Fetal heart sounds were of good quality at 140 per minute. The fetus was in left occipitoanterior position of a vertex presentation. The head was unengaged at the pelvic inlet. The cervix was very soft and dilated 3.5 centimeters. Physical examination revealed no significant abnormalities. The results of urinalysis were normal. The blood pressure was 130/80. Temperature, pulse rate and respiratory rate were normal.

The patient was given demerol 100 milligrams and labor proceeded uneventfully for 6 hours. At the end of this time the cervix was fully dilated and effaced and the head was at the level of the ischial spines. The membranes ruptured spontaneously. It was noted at this time that the amniotic fluid contained fresh blood. Fifteen minutes later the delivery of a normal live infant occurred spontaneously. The third stage lasted 4 minutes and was uneventful. Pituitrin, 1 cubic centimeter was given after the second stage and ergotrate, grains 1/320, (0.2 mgm) after delivery of the placenta. No anes-

Fig. 5. Case 3. In the uterus was found large venous sinus filled with great masses of epithelial squamæ. Hematoxylin and eosin stain. $\times 90$.

Fig. 6. A smear of the top, flocculent layer of blood and mucus from the inferior vena cava of Case 3. A band of mucus characterized by its transparent, veil-like nature shows fine, long parallel fibrils. Wright's stain. $\times 355$.

thetic was administered. For 30 minutes following delivery the patient was alert and communicative. Then there was an emesis of green-tinted fluid. This was followed 5 minutes later by stupor severe by peripheries and coldness and clamminess of the skin. The blood pressure was 40/20. The patient became comatose and pulseless within 15 minutes and respirations were slow and irregular.

At this time about 500 cubic centimeters of bloody fluid were expressed from the uterus and it was believed that shock had occurred from uterine hemorrhage. However blood removed by venepuncture 15 minutes before death had a hemoglobin content of 10.8 grams per 100 cubic centimeters. The plasma protein content was 5.8 grams per 100 cubic centimeters and the hematocrit was 35 by the copper sulfate specific gravity method. Death occurred 1 hour after the onset of symptoms despite antishock treatment.

Autopsy was performed about 1 hour after death. Immediately following the primary incisions and exposure of the abdominal and pleural cavities blood samples were aspirated from the inferior vena cava and from the pulmonary artery. A clean, sterile syringe with a No. 18 gauge needle and clean, sterile specimen bottles with rubber stoppers were used for this purpose.

After autopsy it was felt that death could not be explained on the basis of the gross findings. The uterus was normal for its puerperal state. The placenta and membranes showed no abnormality. There was extensive thrombosis of veins of the broad ligaments. These thrombi were soft of currant jelly type and not attached to the vessel wall. Elsewhere the blood was thin and fluid and no clots were found. The heart weighed 285 grams. Aside from moderate dilatation of the right auricle no abnormality was noted. The lungs were dry and spongy weighing 150

and 80 grams respectively. They were partially collapsed and entirely normal externally and on section. Other organs were essentially normal.

Microscopically there are extensive vascular occlusions beginning with the medium-sized pulmonary arteries and extending down to the alveolar capillaries. The lumina of these vessels are filled with a mixture of loosely packed leucocytes and acidophilic granular material (Fig. 3). Longitudinally-cut hair shafts (lanugo) are found in two of the larger arteries (Fig. 4). This hair is demonstrable in 7 consecutive serial sections of one of these vessels. In 2 smaller arteries the leucocytes appear to be combed-out in parallel rows or lines containing in addition, fine acidophilic granules and a few epithelial squamæ. This "combed-out" appearance of the leucocytes and granules is characteristic of mucus within the vessel. No fat is demonstrable in frozen sections stained with sudan IV.

Although the above findings are present throughout both lungs they are not uniformly distributed. Nevertheless there is very little blood in the pulmonary vascular tree. There is no pulmonary edema. The alveolar spaces and bronchi are empty but in some sections slight atelectasis is present.

In the uterus a very significant lesion is found. A large blood sinus near the endometrial surface contains large masses of epithelial squamæ (Fig. 5).

The liver is noteworthy microscopically because of detachment of sinusoidal endothelium from the liver cords by albuminous fluid with narrowing of the sinusoidal spaces and general ischemia.

Sections of thrombotic veins from the broad ligament show no abnormality of the vessel wall. The thrombi are of very recent origin, show no organization, and no attachment to the endothelium.

No significant abnormality is found in sections of the other organs.

Blood studies The blood aspirated at the beginning of the autopsy did not coagulate. After centrifugation, done within 3 hours after death the sediment showed 3 distinct zones instead of the normal 2. There was a broad more flocculent zone of lighter color above the thin gray layer of leucocytic cream.

Smears were made of the top layer of sedimented material after the supernatant fluid had been removed. These smears were air-dried and stained with Wright's stain and with mucicarmine. The latter stain requires alcohol fixation. The flocculent top layer was then transferred to a small tube and compressed by centrifugation. A portion was fixed in alcohol and the remainder in formaldehyde, and each was embedded in paraffin. The fixed middle, or leucocytic, layer was similarly embedded. Sections were cut and stained with hematoxylin and eosin. Those from the alcohol fixed block were also stained with mucicarmine and phosphotungstic acid-hematoxylin.

Both smears and sections show the bulk of the upper flocculent layer to be composed of finely granular acidophilic material containing widely scattered small clusters of leucocytes. The smears also show occasional, single, long chains or rows of 10 to 20 leucocytes. In one smear of the top flocculent layer of blood from the inferior vena cava, an occasional elongated mass of mucus is found (Fig. 6). The mucus is characterized by its transparent, veil-like nature showing very fine, long parallel fibrils all of which stain pink with mucicarmine. There are many eosinophiles in and about the masses of mucus.

In the sections of the alcohol fixed blood sediment which were stained with hematoxylin and eosin there are small clumps of fine and coarse granules of golden yellow (bile) color. Thin wavy fragments, characteristic of squamæ, are found in the sections but not in the smears. These stain red with eosin and yellow brown with phosphotungstic acid-hematoxylin. (It is to be remembered that the latter stains fibrin blue.)

Smears and sections of the middle zone which consists of leucocytic cream, show no abnormal findings.

DISCUSSION

The work of Steiner and Lushbaugh (5) has established maternal pulmonary embolism by amniotic fluid as a distinct pathological entity which is to be suspected clinically in every case of sudden severe shock during labor or the immediate puerperium. These authors pointed out that this catastrophe is one of the most common causes of death during labor and within the first nine hours thereafter. This opinion was based on an incidence of 1 in 8,000 obstetric cases over a period of 9 years at the Chicago Lying in Hospital. However because the diagnosis was made only in cases in which autopsies were performed the frequency of occurrence is probably considerably greater.

It is an almost incredible but a significant coincidence that the 3 cases reported here occurred consecutively within 1 year in a general hospital averaging 1200 to 1300 deliveries annually and they represent all the maternal deaths on the obstetrical service within that time.

Steiner and Lushbaugh (5) contended that many unrecognized nonfatal cases do occur. Furthermore in patients on whom autopsies were not done it is probable that a sizeable percentage of maternal deaths labeled thrombotic pulmonary embolism, obstetric shock or postpartum hemorrhage are actually fatalities due to pulmonary embolism by amniotic fluid. Even after a postmortem examination it is possible that the disease can escape recognition unless it is kept in mind.

At the present time the clinical diagnosis cannot be made before the appearance of shock. In the cases here reported the patients entered labor with no apparent complication except for moderate hydramnios in Case 2. In Cases 1 and 2 tetanoid contractions were observed late in the second stage. It was noted by Steiner and Lushbaugh (5) that such contractions were a frequent prelude to the shock state. In Case 3 the amniotic fluid contained blood. This supports the theory that the immediate predisposing factor of this disease is a communication between the uterine venous sinuses and the amniotic cavity. Shock occurred suddenly and without warning near delivery or soon thereafter and was irreversible. In 2 of these cases death was attributed clinically to postpartum hemorrhage since much bloody fluid was expressed from the uterus after shock was manifest. However the amount of hemorrhage was small and the hematocrit hemoglobin content and the plasma protein value of the antemortem blood sample in Case 3 were not consistent with exsanguination. The phenomenon of blood in coagulability described in terminal shock (4) was a striking feature in all 3 cases.

The gross findings of the postmortem examination of these 3 patients and of all the cases thus far reported have failed to explain the cause of death. Microscopically the disease is limited to the pulmonary arteries, arterioles and capillaries. The involved vessels are

bloodless and are occluded by emboli consisting of abundant polymorphonuclear leucocytes mucus bile-stained debris (meconium) epithelial squamæ, lanugo hair and granular debris with or without fatty elements. The character of the embolic picture is variable. Which of these materials are present in any given vessel depends upon the proportion of meconium, vernix caseosa and debris in the amniotic fluid and upon the heterogeneous distribution of these elements in the circulating blood. Often enough the vascular obstructions in the smaller branches consist of leucocytes alone. The source of these leucocytes is obscure. Inasmuch as they are also found in great numbers in the larger pulmonary arteries their origin is probably extrapulmonary.

The sections of liver from Cases 2 and 3 show the microscopic picture of serous hepatitis (Roessle) which occurs frequently in cases of sudden death following shock. The liver sinusoids and portal venules of Case 2 contain polymorphonuclear leucocytes and granular material a picture similar to that seen in the lung.

Blood from cases of pulmonary embolism by amniotic fluid removed from the right side of the heart or the inferior vena cava and subjected to centrifugation may show 3 strata in the sediment. The presence of 3 instead of 2 strata should be considered pathognomonic of this condition. The particulate constituents of amniotic fluid including mucus, being of low specific gravity settle out as a flocculent layer above the leucocytic cream. It is recommended that both smears and sections be made of this layer. The sections should be cut from alcohol as well as Zenker or formalin fixed blocks of this sediment. The stains should include Mayer's mucicarmine for the identification of mucus, Mallory's phosphotungstic acid-hematoxylin for the differentiation of fibrin from mucus and epithelial squamæ and hematoxylin and eosin for routine purposes.

The utility of this procedure is twofold. In cases in which permission for autopsy cannot be obtained it may be possible to secure

blood from the right heart by aspiration. The blood examined by the method described may become the only means for a positive diagnosis. In cases in which autopsy permission is granted this procedure serves to re-enforce the diagnosis.

Such postmortem aspiration and examination of blood from the right heart, adopted as a routine procedure in obstetrical deaths, may furnish desirable information regarding the frequency of embolism by amniotic fluid.

SUMMARY AND CONCLUSIONS

Three cases of pulmonary embolism by amniotic fluid are reported. They were characterized by the sudden, unexpected development of irreversible shock during labor or the immediate puerperium, and were followed very quickly by death. At autopsy no significant gross abnormality could be found. Microscopically the diagnosis was established by the demonstration of extensive vascular occlusions by leucocytes and constituents of amniotic fluid in the smaller branches of the pulmonary arteries.

The sediment of blood aspirated from the pulmonary artery and the inferior vena cava of one of these cases showed a pathognomonic, third flocculent stratum above the layer of leucocytic cream. In smears and sections of this stratum constituents of meconium and amniotic fluid are demonstrable.

In cases of obstetrical death, routine aspiration and examination of blood from the right heart by the method described may establish the diagnosis of pulmonary embolism by amniotic fluid when autopsy cannot be performed. In this way the frequency of this condition may be determined more accurately.

THE PLASTIC SURGICAL CLOSURE OF DECUBITUS ULCERS IN PATIENTS WITH PARAPLEGIA

ROBERT H. CLIFFORD III M.D. JEROME GELB M.D.
JULIUS M. JOSEPH, M.D. and LEO L. LEVERIDGE, M.D.
New York, New York

THE excision and closure of decubiti in patients with paraplegia by plastic surgical methods is one of the interesting and valuable contributions made by military surgeons during World War II. The first report of bold surgical attack upon an anesthetic bed sore in the paralytic was published by Lamon and Alexander in 1945. However it is stated in the literature that the case cited was housed in the neurosurgical section of the McCaw General Hospital which was under the direction of W. B. Scoville. Many who are familiar with the work of Scoville at the Cushing General Hospital during the recent war feel that priority should be given him for introducing the idea of the surgical treatment of decubitus. Undoubtedly Charcot's concept (1879) of a neurogenic, trophic factor presumed to be responsible for the development of decubitus in denervated areas caused surgeons to hesitate to attack these lesions surgically in civilian practice as well as in military practice in the early years of the war.

As these unfortunate wounded accumulated in Army hospitals during the war Scoville's work became known. Subsequent reports have attested to the value of the methods of plastic surgical excision of decubiti in paraplegics. In 1945 White Hudson and Kennard (15) reported 5 such cases in which patients were treated successfully by excision and the advancement or rotation of flaps of adjacent skin and subcutaneous tissue. Croce Schullinger and Shearer (1946) reported 8 cases in which the decubiti were excised and the defects were closed by the advancement of multiple regional flaps of skin and subcutaneous tissue. Poer

(1946) reported on the incidence of decubiti in patients paralyzed due to war injuries. Forty four (57.1%) of 77 patients with gunshot injuries of the spinal cord had decubiti. Barker Elkins and Poer (1946) reported their results in 70 cases in which decubiti were treated by simple excision and suture by rotation flaps or by the free grafting of skin. White and Hamm (14) (1946) published their experiences with 14 decubiti in 9 patients treated by simple excision and closure or by sliding flaps. Gibbon and Freeman reported on the operative closure of 65 ulcers in 43 patients.

Much information has been gained from a study of these reported groups of cases. The organized plan of the United States Army Medical Department for the care of paralyzed individuals as outlined in Poer's publication has resulted in obtaining the maximum benefit of neurosurgery for these patients, and a high percentage of them have been spared the serious complications of the genitourinary tract. They have been benefited by exercise by physical therapy by general supportive measures and some have been completely rehabilitated. Many of these patients have now been transferred to Veterans' hospitals where they continue to receive the benefits of physical therapy and are undergoing rehabilitation. The closure of long persistent or recurrent decubiti in these chronic cases is the present problem of paramount importance. The continued loss of protein and nitrogen from open wounds is the causative factor underlying the debility of the patients. The excellent studies of Mulholland and CoTu, Wright Vinci and Shafiroff demonstrated that in patients with decubiti, the plasma protein concentrations invariably are below normal and that a negative nitrogen balance exists.

From the Plastic Surgery Service of the Veterans' Administration Hospital, Kingsbridge Road, Bronx, New York.
Read before the Surgical Section of the New York Academy of Medicine, February 7, 1947.

Because the surgical treatment of decubiti in paraplegics involves the transposition of soft tissues supplemented occasionally by the use of free grafts of skin this surgery has been the responsibility of the plastic surgeons. At the Veteran's Administration Hospital in the city of New York there have been 65 patients with paraplegia, 59 of whom have had 298 decubiti. This report deals with the surgical management of these patients. Their ulcers have been of long duration resistant to conservative treatment and in a few cases recurrent after surgical excision and repair. In comparison with the reports referred to above it is apparent at once that the decubiti in this group of patients are of longer duration than those encountered in Army and Navy hospitals during the war. Included in this group of patients are those who have failed to be rehabilitated physically and mentally some who have been lacking in morale and in co-operation and a few who have developed harmful habits such as alcoholism. Despite these circumstances the results following surgery have been gratifying.

ETIOLOGY

There is general agreement that pressure over osseous prominences such as the trochanter the sacrum or the anterior superior spine is the most important single factor in the development of decubitus. Compression of the soft tissue overlying bone causes local anemia which if sufficiently prolonged results in necrosis. Also there is general agreement that old age general debility avitaminosis malnutrition and anemia are contributing factors.

However there is difference of opinion regarding the pathogenesis of decubitus in paraplegia. Gibbon and Freeman basing their conclusions on the work of Brown Sequard, Paget and Cohnheim feel that neurogenic factors are not responsible but that decubiti in paraplegics are due to continued local pressure associated with loss of motion and of muscle tone. Munro elaborating on the neurogenic theory first advanced by Charcot, feels that the development of a decubitus in a paraplegic is dependent on the effect of abnormal vascular reflexes caused by disturbance of the

sympathetic nerves of the area. He points out that in his series of cases with injury to the thoracic and lumbar spinal cord the incidence of bedsores was 54 per cent while in the cases with injury to the cervical cord the incidence was only 20 per cent. He states that there is failure of the proper response of circulation of the skin to its varying needs and that this failure is due to a reflex of the sympathetic nerves. According to this theory spinal shock, present immediately after injury affects the peripheral vasomotor reflexes with the failure of development of increased regional flow of blood which is necessary for proper nutrition of the part. However Munro agrees that all bedsores start as pressure sores and may be prevented by turning the patient hourly by regular massage by keeping the skin dry and by the use of powder. MacCollum feels that pressure causes a local diminution of blood supply resulting in necrosis of the skin and underlying tissues. Boyd calls the condition a pressure gangrene which is influenced by a devitalized condition of the tissues as a result of old age long illness, or of hypostasis secondary to feeble circulation. In spinal cord lesions, he believes that capillary stasis from injury to vasomotor nerves is a contributing factor.

PATHOLOGY

In the early stages of decubitus, continued pressure produces thrombosis of small blood vessels. In the affected area a reddish patch appears which soon changes to a dusky color and necrosis follows. Slough separates gradually to leave a granulating surface. The granulation tissue of the ulcer is infected and is grey in color. As the ulcer increases in size the slough extends farther in subcutaneous areas than in the adjacent skin so that one may be deceived concerning the size of the lesion. Also the ulcer extends toward the deeper layers of tissue so that eventually the underlying bone is exposed. The appearance of the base and the undermined sides of an ulcer of long duration gives the impression of an open sac with a smooth lining. Photograph of a specimen of decubitus ulcer which was excised at operation is shown in Figure 1. The specimen has the gross appearance of a cyst

Fig. 1 Specimen excised from a patient with decubitus over the trochanter of the femur. Note the cyst-like character of the lesion.

with a relatively small opening through the skin. Its thick walls consist of fibrous tissue and its lining is of smooth grey avascular granulation tissue. On microscopic section it is observed that the smooth appearance is due to a lining of necrotic tissue and pus superimposed on an area denuded of skin. The underlying and adjacent connective tissue is edematous but well vascularized. There is infiltration of polymorphonuclear leucocytes, lymphocytes, and plasma cells with occasional histiocytes. The arterioles have thick walls. There is proliferation of fibrous tissue throughout. The capillaries and venules are dilated and engorged. Undoubtedly this stasis of blood contributes to the extension of the ulcer. Photomicrographs of ulcer tissue are shown in Figures 2 and 3.

BACTERIOLOGY

The causative organisms assume an important rôle when the appearance of the ulcer indicates spreading infection and when there is evidence of systemic reaction. The necrotizing skin and underlying tissues are contaminated with bacterial flora of the skin and intestinal tract. These invade the deeper tissues as the process extends. The presence of anaerobic streptococci may cause an inflammation which progresses rapidly with resultant extensive gangrene. Careful anaerobic and aerobic cultures should be taken in such

Fig. 2 Low power photomicrograph of the edge of a chronic decubitus. The marginal epithelium is embedded in dense fibrous tissue.

cases so that specific treatment may be instituted immediately after excision of the gangrenous tissue. Also it is advisable to deter

Fig. 3. High power photomicrograph of tissue from the floor of a decubitus of 12 months duration in a patient with paraplegia due to gunshot wound of the spinal cord. Marked capillary dilatation and stasis is in evidence.

mine the susceptibility of the causative organisms to penicillin, to streptomycin and to the new antibiotic bacitracin.

In the indolent ulcers one finds a wide variety of organisms. Anaerobic and aerobic studies were made of the flora of the ulcers in 18 cases in this series. A variety of organisms were reported in the following order of frequency: staphylococci (usually coagulase positive), *Bacillus proteus*, *Escherichia coli*, *Bacillus pyocyaneus*, diphtheroids, hemolytic streptococci and nonhemolytic streptococci. In addition in 9 of the cases the anaerobic plates showed the pinpoint colonies of microaerophilic streptococci. Bacteriologic studies made by Gibbon and Freeman and by White and Hamon (14) revealed similar findings. In the cleansing of an indolent decubitus ulcer in preparation for surgery the frequent change of saline compresses has been found to be most useful.

Specific types of infection have called for specific local therapy. Dressings of zinc peroxide have been very effective in clearing up areas where there was gangrene of tissue in association with anaerobic organisms. Appli-

cation of parachlorophenol has been used effectively to combat heavy growth of the *Bacillus pyocyaneus*. Nine-amino acridine hydrochloride is effective against most of the other organisms which have been recovered from decubiti in this series of cases.

PREOPERATIVE AND POSTOPERATIVE CARE

In preparation for surgery a high caloric diet with extra nourishment is given in an attempt to restore a positive nitrogen balance. Transfusions of blood, of plasma, and protein digests are indicated for the treatment of hypoproteinemia and anemia. Vitamins (B complex and C) liver extract and iron are administered. Patients with good appetite and steady gain in weight are considered to be ready for operation. Only those patients in whom complications of the urinary tract have been avoided or controlled are subjected to operation.

Many of the patients in this series demonstrated involuntary spasms of skeletal muscles. In several such cases these spasms constituted a factor which contributed to the development of complications in the wounds.

Fig. 5 a, above, Small decubitus over the anterior superior spine of the ilium in a patient with transection of the spinal cord. t the level of twelfth Thoracic. b Result after elliptic excision of the decubitus and linear closure of the defect. This method was found useful only in the management of small ulcers. It was successful in 74 per cent of the cases in which it was used.

following surgical closure. Such spasms have resulted in partial or complete separation of the edge of a wound and in a few of these cases bursae have developed under the flaps of soft tissue. Therapy with penicillin and sulfonamides is given for 24 hours prior to operation. The preparation of the wound includes daily cleansing with saline sponges and the application of a fine mesh gauze impregnated with xeroform ointment. Slough is excised at the time of each dressing. Specific infectious agents require the use of specific local therapy as mentioned above. Cleansing enemas are given prior to operation.

In the care after operation the measures described in the preparation for operation are continued. Penicillin is administered throughout the postoperative period. The position of

Fig. 6 Diagram of the method of excision of decubitus ulcer and closure by pedicled flap.

the patient when returned to bed must be supervised carefully. The success of surgery depends upon the avoidance of those factors which in themselves contributed to the development of the original decubitus. The patient must be moved from side to side and from prone to supine. It is inadvisable to allow the weight of the body to cause pressure over the operative site until the wound is inspected at the time of the first dressing. Gross soiling of the operative area is prevented by the use of a retention catheter by administration of a low residue diet and by the giving of liberal doses of paregoric. Enemas are withheld until the 7th postoperative day. The first postoperative dressing is done on the 6th, 7th or 8th day after operation at which time alternate sutures are removed. The last sutures are not removed until the 14th day after operation. Collections of fluid or clot are aspirated and solution of penicillin is instilled.

STATISTICS

Sixty five patients with paraplegia are included in this analysis. Fifty nine of these have had 298 decubiti. Six patients had no pressure sores. Of these 59 patients all but 3 had unhealed decubiti at the time of admission to this hospital. Forty nine had multiple decubiti while only 10 patients had a single decubitus. Six of these patients had lesions of the cervical cord. 53 had lesions of the dorsal or lumbar spinal cord. Of those with lesions of the cervical cord 3 exhibited multiple ulcers. 1 patient had only 1 ulcer and 2 patients had none at all.

Of interest is the location of the 298 decubiti which occurred in the 59 patients (Figure 4)

Fig. 7 a, above, Appearance of chronic decubitus over the sacral region in a patient with paraplegia due to transection of the dorsal spinal cord. b, Result after excision of the decubitus and closure by rotation of pedicled flap with primary closure of the defect created by the construction of the flap. Objection to this method is based on the fact that tension at the line of suture laterally may be reflected to the medial line of suture which resides close to the site of the original decubitus. This method was successful in 62.5 per cent of cases in which it was used.

Fig. 8 a, above, Decubitus of left buttock in patient with paraplegia due to gunshot wound of dorsal spinal cord. The relatively small external opening with deep extension into the underlying tissue was common characteristic of the decubiti over the ischial tuberosities in the group of cases included in this report. b, Appearance after excision of the ulcer and sinus and closure by advancement of flap from neighboring tissue as shown in Figure 6. This method was successful in only 62.5 per cent of the cases in which it was used.

Fig. 9. Diagram of the method of excision of decubitus and closure by pedicled flap with free thick-split graft at a distance. The method has the advantage that lines of suture are without tension and do not reside over the area of primary decubitus. The free graft effectively provides a permanent surface for the soft tissues underlying it. This method was successful in 75 per cent of the cases in which it was used.

osity, the tibia, and the anterior superior spine have been operated upon (Table I). The largest ulcer encountered in this series of cases was 12 by 15 centimeters. In a few cases the ulceration was quite small but often such an ulcer represented the opening of a deep sinus. In one case such a sinus with an opening only 1 centimeter in diameter was found to extend to a depth of 14 centimeters. Forty or 71 per cent are healed following surgery. In these patients the ulcers had been present for an average time of 12 months. In 16 or 29 per cent the ulcer persisted or recurred following excision and closure. In these patients the average length of time between the onset of the ulcer and the date of operation was 15 months.

OPERATIVE TREATMENT

The operative treatment of decubitus consists of the complete excision of the ulcer and adjacent scar and the covering of the defect with an adequate pad of healthy tissue. By this is meant a covering of skin with a thick layer of subcutaneous fat. Usually this can be advanced from surrounding tissues but con-

Fig. 10. a, above, Decubitus of 10 months' duration over the trochanter of a patient with paraplegia due to gunshot wound of the spine at the level of the 4th thoracic segment. Fragmented bone was exposed in the base of the ulcer. b, Result after excision of decubitus and closure by pedicled flap with free thick-split graft at the site of elevation of the flap. Note that by the use of this method the graft resides permanently over soft tissues, not over a bony prominence.

ceivably might be transplanted from a distance.

The complete excision of the ulcer may be a difficult technical procedure. Ulcers of long duration are surrounded by a dense layer of scar and usually the ulceration has undermined the regional soft tissues extensively. Subcutaneous excavation of the ulcer may extend as far as 14 centimeters beyond the margins of the ulcer itself. Ulcers over the trochanter or ischial tuberosity often are associated with fragmentation and necrosis of bone necessitating partial osteotomy as a step in excision of the ulcer. Because of the profuse bleeding from scar tissue at the time of excision it has been our practice to administer a

This method was successful in only 62.5 per cent of the cases in which it was used.

The most frequently encountered decubitus was that of the sacral region. Sixty three (21 per cent) were in this area. There were 57 (19 per cent) ulcers over the trochanters. Also there were 57 (19 per cent) over the os calcis. It is of interest that 26 patients had ulcers

over both heels while only 5 showed ulceration over only one heel. With one exception these ulcers responded to conservative therapy healing spontaneously. There were 30 ulcers (10 per cent) over the ischial tuberosities, 23 ulcers (8 per cent) over the knee, 19 ulcers (6 per cent) over the anterior superior spine of the ileum, 11 ulcers (4 per cent) in the pretibial areas, and 38 ulcers (13 per cent) were distributed in various areas of the paralyzed torso or extremities.

An analysis of those cases in which the ulcers were treated by excision and plastic surgical closure is of interest. Thus far 56 ulcers over the sacrum the trochanter the ischial tuber

ceivably might be transplanted from a distance.

The complete excision of the ulcer may be a difficult technical procedure. Ulcers of long duration are surrounded by a dense layer of scar and usually the ulceration has undermined the regional soft tissues extensively. Subcutaneous excavation of the ulcer may extend as far as 14 centimeters beyond the margins of the ulcer itself. Ulcers over the trochanter or ischial tuberosity often are associated with fragmentation and necrosis of bone necessitating partial osteotomy as a step in excision of the ulcer. Because of the profuse bleeding from scar tissue at the time of excision it has been our practice to administer a

Fig. 1. Diagram of the technique of excision and closure by Z-plasty. Because the defects following excision of decubitus usually are quite broad this method of closure is not considered to be ideal. It is successful in only half of the wounds to which it was applied.

transfusion of blood during the operation. Hematoma as a complication may lead to failure of the operative effort. Therefore emphasis must be placed on accurate hemostasis. Electrocoagulation has been used for this purpose but the authors feel that its use is not ideal since it leaves traumatized or necrotic tissue in the wound. Its use in this series of cases was followed by excessive accumulation of serum in the wounds. Hemostasis is effected best by the use of mosquito clamps and fine ties of No. 00000 plain catgut or No. 120 cotton.

The operative procedures which have been used in the 56 operations in this series are 5 in number. These procedures are based upon established principles of plastic surgery. They are as follows: (a) elliptic excision and closure; (b) excision and closure by Z-plasty; (c) excision and closure by pedicled flap; (d) excision and closure by pedicled flap with free graft at a distance; (e) closure by free skin graft. Emphasis has been placed on the necessity for covering the site of ulceration with a generous flap of tissue and without scars of suture overlying the original site of ulceration. To accomplish this a free thick split graft of skin at the site of procurement of the flap has

Fig. 2. a, above, The dotted circle represents the size of the derubritus over the trochanter in this case. The lesion is present 1 month. It is excised and the defect closed by Z-plasty. b, Appearance 3 months after excision of the decubitus and closure by Z-plasty.

allowed for its rotation or advancement without tension. Free grafts applied directly to the decubitus have been used only in those cases in which the patient was too sick to undergo major surgery. Others have pointed out the value of this method calling attention to the facts that it provides wound closure and permits stabilization of altered body chemistry. Diagrams of steps involved in these five operative procedures are outlined in Figures 6, 9, 11, 13, and 15. Photographs of lesions before and after operation are shown in Figures 5, 7, 8, 10, 12, 14, and 16.

RESULTS

Elliptic excision has been used only in the management of very small ulcers. This method was applied in 23 cases with complete

Fig. 13. Diagram of the method of excision of decubitus and closure by a double pedicled flap with free graft at a distance. This method represents a variation of that shown in Figure 9 and it has the same advantages.

healing in 17 or 74 per cent. The value of closure by Z-plasty has been limited. This principle does not often apply to closure following the excision of decubiti as the resultant defect may be quite broad. Z-plasty was used in 4 cases. Three were trochanteric ulcers and 1 was an ulcer over the ischial tuberosity. The operation was successful in 2 cases and in 2 cases failure resulted.

Excision and closure with a pedicled flap and primary closure of the defect caused by rotation of the flap was successful in only 5 (62.5 per cent) out of 8 cases. Healing was effected by this operative technique in 2 cases of sacral ulcer and 3 cases of trochanteric ulcer. The failures occurred following the use of this method in 3 cases of ulcer over the ischial tuberosity. It is felt that the use of a free graft to cover the defect from which the flap was rotated might have effected satisfactory healing in these cases. Considering the size and location of the ulcers the impression has been obtained that excision and closure by a pedicled flap with a free graft at a distance is the best method available. By this method the thick-split graft resides permanently over soft tissue which is not subjected to the pressure of a bony prominence. This method was used in 16 cases with complete healing in 12 (75 per

Fig. 14. a, above, Appearance of decubitus of left trochanteric region in a patient with paraplegia due to a lesion at the level of the eleventh thoracic segment of the cord. b, Appearance 6 weeks after excision of the decubitus and closure by the advancement of a double pedicled flap with free graft over the soft tissues from which the flap was raised as outlined in Figure 13.

cent) and failure in 4 cases (25 per cent). This method was used in the management of 6 sacral ulcers, 9 trochanteric ulcers and 1 tibial ulcer. The use of free skin grafts (thick-split) is reserved for those cases in which the patient was too sick to undergo major surgery. The value of the method lies in the fact that it is a minor operative procedure, a closure may be obtained with resultant stabilization of altered physiology. Though this closure is followed by improvement in the general condition of the patient, it does not provide a closure of sufficient strength to withstand the constant trauma to which the area is subjected in the paralyzed patient. Therefore it is looked upon as a closure of temporary value. It is used in the excising the graft at a later date and covering the formerly ulcerated area with a thick-

Fig. 5 Diagram of the method of temporary closure of decubitus by the application of multiple small thick split grafts of skin. Free grafts were used only when the general condition of the patient was such that major operative procedure was contraindicated. Upon the degree of irregularity of the granulation tissue of the decubitus rested the decision as to whether the wound was surfaced by single large graft or by multiple small grafts. The method allowed for the early restoration of altered protein metabolism and therefore is useful as a temporary measure. Grafts were successful in 4 out of 5 decubiti to which they were applied. Recognition of the fact that free grafts cannot be expected to withstand daily trauma to bony prominences in paralyzed patients is planned to excise such grafted area at a later date and to cover the defect by pedicled flap, diagrammed in Figure 6.

flap of skin and subcutaneous tissue. The fact that healing followed in only 4 of the 5 cases in which free grafts were used is not considered of statistical significance for the reason that the method was used only in the management of ulcers in those patients with extreme general debility.

Study of Table III shows that ulcers in the sacral area have been healed effectively by operative surgery in 88 per cent of cases. The closure of ulcers in the trochanteric area was successful in 77 per cent of cases. Ulcers in the region of the ischial tuberosity were closed successfully in only 46.6 per cent of cases in the series.

An analysis of the complications which resulted in failure in 16 cases following operative closure is of interest. These complications were as follows: hematoma of wound, 4 cases; undue tension in line of suture, 6 cases; uncontrollable spasm of extremities, 2 cases; massive infection, 2 cases; partial necrosis of flaps, 1 case; lack of co-operation of patient, 1 case.

DISCUSSION

Attention has been called to the fact that complete healing followed in 40 (71 per cent)

Fig. 6 a, above. Decubitus over the sacral area in a patient with paraplegia due to a lesion of the spinal cord at the level of the second thoracic segment. Despite continued supportive therapy with transfusion of plasma and blood supplemented by the giving of amino acids and protein dexters this patient had severe anemia and marked hypoproteinememia. For this reason it was not deemed advisable to subject this patient to major operative procedure. b, Appearance of the sacral area after closure of the decubitus by the application of multiple small thick-split grafts of skin. The general condition of the patient improved rapidly following healing of the wound, and at the time of this report he is a candidate for excision of the grafted area so that the bony prominence may be protected ultimately by a thick pad of soft tissue.

of the 56 decubiti treated by excision and plastic surgical closure. Only those ulcers which had failed to heal after conservative management for a minimum of 10 months were subjected to surgery. It has been observed repeatedly that decubiti of long duration are associated with pallor of the granulation tissue, excessive scar in the floor and at the margins of the ulcers, and with thinning of the skin and subcutaneous tissue adjacent to the ulcers. In the report of Croce, Schul-

TABLE II — RESULTS FOLLOWING EXCISION AND PLASTIC CLOSURE

Type of closure	No. cases	Complete healing	Failures

linger and Shearer the interval of time between onset of the ulcer and the date of surgical excision in 7 patients averaged 80 days. Barker, Elkins, and Poer reported complete healing following surgery in 39 (76.4 per cent) of 51 cases. The interval of time between the onset of the ulcer and date of operation is not given. Because their patients were treated in Army hospitals during the war it is presumed that the majority of the decubiti were of short duration. White and Hamm (14) reported complete healing following surgery in 6 (42.8 per cent) of 14 cases, partial healing in 6 (42.8 per cent) and failure in 2 cases (14.2 per cent). Gibbon and Freeman reported primary healing following surgery in 44 (67.7 per cent) of 65 cases, delayed healing in 10 cases (15.3 per cent), improvement in 5 cases (8 per cent), failure in 5 cases (8 per cent), and death in 1 case (1.5 per cent). In view of the fact that in the cases reported herein the ulcers were of long duration and had exhibited no tendency to heal under conservative measures, the success of surgery in 71 per cent of cases attests to

the soundness of surgical attack upon chronic decubiti in patients who are suffering with paraplegia.

SUMMARY AND CONCLUSIONS

Report is made of experience with the excision and plastic surgical closure of 56 decubiti in paraplegic patients in a veteran's hospital. The locations of decubitus ulcers studied, their etiology, pathology and bacteriology are discussed.

Five methods of operation have been used: elliptic excision and closure, excision and closure by Z-plasty, excision and closure by pedicled flap, excision and closure by pedicled flap with free graft at distance, closure by free thick-split graft of skin. Forty, or 71 per cent of the 56 cases were healed by these procedures.

All of the ulcers in this series were of long duration. They had been present for an average of 12 months in 40 cases in which plastic surgical closure was successful. The ulcers had averaged 15 months in duration in 16 cases (29 per cent) in which plastic surgical closure was not successful. In the management of this group of patients emphasis has been placed upon the application of the established principles of plastic surgery to the closure of the decubiti. Experience has indicated that methods in which the scar of suture resides directly over the site of the former decubitus are apt to be unsuccessful. Elliptic excision was used only in the management of small ulcers. Free graft of skin was used only in the care of ulcers in patients whose general condition would not permit major operative procedure. Evidence in this report indicates that large ulcers are closed successfully in the highest percentage of cases when a flap of skin and subcutaneous tissue is rotated from an adjacent area and the defect at the site of procurement of the flap is surfaced by a free graft of skin.

SARCOMAS OF THE SMALL AND LARGE INTESTINE

J RABINOVITCH M.D. C.M. D.M. GRAYZEL, Ph.D. M.D. A.J. SWYER, M.D. and
B. PINES M.D. Brooklyn New York

THE basis of this paper is a study of 15 cases of sarcoma of the small and large intestine this includes 9 cases of sarcoma of the small intestine 5 of the colon and 1 of the rectum. It comprises all the cases collected from the records of the Jewish Hospital in the past 25 years. During the same period there were admitted to the hospital 48 patients with carcinoma of the small intestine 1 377 with carcinoma of the colon and 577 with carcinoma of the rectum. According to these figures the relative proportion of sarcoma to carcinoma of the small intestine is approximately 1 to 55 of the colon 1 to 275 and of the rectum 1 to 577. It appears that even in the case of the small intestine the relative incidence of carcinoma is considerably greater than that of sarcoma although it is generally believed that sarcoma of the small intestine is of more frequent occurrence than is carcinoma. The number of cases of sarcoma presented in this series may be too small to draw any definite conclusions as to the incidence of this lesion in the bowel but it is nevertheless quite significant. Many of the observations recorded here are largely confirmatory of the information already available in the voluminous literature on this subject (3). However additional emphasis will be placed upon those aspects which appear to warrant it.

There are no definite pathognomonic signs symptoms or laboratory criteria on which a diagnosis of sarcoma of the bowel can be made before operation. The onset of the disease, although usually insidious may be acute, and the symptoms may vary in duration from several days to several years. These patients present various forms and locations of their tumors. A study of the cases reveals that the lesion may occur in all age groups although it is most frequent in middle or past middle life. The youngest patient in our series was a 16

year old girl and the oldest a 72 year old male, the average age incidence being 54 years. More than 65 per cent of the patients fell in the age group of 50 to 70 years. These figures are in close agreement with other figures reported in the literature.

It is generally conceded that sarcoma of the intestine occurs more frequently in males (1). In the cases reviewed here there was no appreciable difference in the distribution of the disease in the two sexes. There were 8 males and 7 females showing a slight preponderance among males.

It has been the observation of many investigators that the incidence of the ratio of sarcoma of the small intestine to sarcoma of the large intestine is approximately 2:1 (2). In the series reported here there were 9 instances of sarcoma of the small intestine 2 of the appendix, and 3 of the large bowel a proportion of approximately 2 to 1 in favor of the small intestine.

The etiology of sarcoma of the bowel is still unknown although it is believed by some that trauma may play a part in its development. So far as the cases reported here are concerned no history of injury was recorded in any of the patients.

A study of the cases reported in this series has emphasized in our minds the difficulties one encounters in being certain that a given tumor is sarcomatous or carcinomatous. The onset of the disease was usually insidious in character and clinical evidence of its existence did not appear until late. When the onset was acute and the symptoms of short duration there was always present some complicating factor to account for its acuity. Thus in one patient with lymphosarcoma of the appendix, and in another with a neurofibrosarcoma of the rectum the disease was heralded by a profuse intestinal hemorrhage associated with dizziness fainting and profound weakness. Two other patients with lymphosarcoma of the ileum developed acute intussusception and

only then they first became aware of the existing disease. The majority of the patients however pursued a more chronic course which lasted from several weeks to 2 years.

Blood in the stools appearing as gross hemorrhage or melena was a significant finding in 8 patients in 2 others it was not reported. Patients with bleeding usually complained of weakness and dizziness, and on physical examination showed a variable degree of pallor which was proportionate to the loss of blood. The hemoglobin content of the blood was low and in one instance reached a level of 37 per cent requiring several blood transfusions. The nutrition was fairly well maintained in most of the patients, although some complained of a moderate loss of weight.

Pain frequently described as cramp-like in character was significant in 11 of the 15 patients recorded. The distribution of the pain varied although it was usually confined to the area involved by the tumor. Anorexia nausea and vomiting were infrequent complaints. Constipation diarrhea or both were more common. Many of the patients with constipation resorted to cathartics, and this may account for the occurrence of diarrhea in some of the patients.

A palpable mass was noted in 9 of the 15 patients. The location of the mass varied and was not always constant. In 4 instances it was felt in the right lower quadrant of the abdomen in one, around the umbilicus, right upper and left lower quadrants, respectively. In one instance the mass was palpated in the anterior wall of the rectum and in another it was visualized as a cauliflower bleeding growth in the sigmoid on sigmoidoscopic examination. In many cases the mass was tender to palpation and was fixed in position or freely movable.

Röntgenography was of considerable aid in the diagnosis of these tumors. The roentgenologic appearance of the lesion showed great variations in different cases. In some it presented a mere filling defect or a moth eaten irregularity in the bowel wall. In others the affected bowel appeared as a rigid tube or showed abnormal retention of barium.

In none of the cases reported here was a correct clinical diagnosis made before opera-

tion. Among the various diagnoses made preoperatively were colitis, carcinoma, ovarian cyst, bleeding duodenal ulcer and subacute appendicitis. It is significant that the tumor simulates a number of closely allied diseases of the intestine and renders correct diagnosis most difficult.

In this study the following types of intestinal sarcoma were encountered: lymphosarcoma, 4; leiomyosarcoma, 7; reticulum cell sarcoma, 3; neurofibrosarcoma, 1; a total of 15. The tumors were found in the following locations: jejunum, 2; ileum, 7; appendix, 1; colon, 2; sigmoid, 1; and rectum, 1.

It is the consensus that lymphosarcoma is more frequent of occurrence than are the other forms of sarcoma of the intestine, this holds particularly true in the case of the small intestine. It did not hold true however in the present series. While the lymphosarcoma and reticulum cell sarcoma were particularly common in the small intestine the leiomyosarcomas on the other hand were equally common in the small and large intestine. No cases of lymphosarcoma were noted in the large bowel excepting in the appendix. Since lymphoid tissue forms an important part of the appendix one should expect to find an appendiceal form of lymphosarcoma.

Leiomyosarcoma originates in the smooth muscle cells of the musculature. It is usually slow growing and often well demarcated from the other layers of the intestinal wall. In the present series, there were 7 cases of leiomyosarcoma, 2 occurred in the ileum, 1 in the jejunum, 1 in the appendix, 1 in the cecum, 1 in the transverse colon and 1 in the sigmoid. In 3 of the cases the lesion presented itself as a pedunculated polypoid growth arising by a narrow or broad base from the inner surface of the bowel and partly encroaching upon its lumen. The free surface of the tumor was at times smooth and at others necrotic and ulcerated. In the remaining cases, the neoplasm consisted of a homogeneous mass, grey or pink in color and arising from the muscular coat of the bowel. The mucosa overlying the tumor was sometimes well preserved and apparently unaffected by the growth. On occasions however the mucosa was infiltrated with tumor tissue became ulcerated and

Fig. 1. Photomicrograph of leiomyosarcoma. Hematoxylin and eosin stain $\times 80$.

Fig. 2. Higher magnification of Figure 1. Note tumor giant cells. Hematoxylin and eosin stain $\times 215$.

showed scattered hemorrhages. The tumor was usually firm in consistency; in the more rapidly growing forms it tended to become soft and necrotic. The direction of growth was not always uniform. In 2 cases it protruded into the lumen and in the remaining ones it grew outwardly forming a bulge on the exterior of the bowel.

Histologically these tumors can be traced to the muscular coat of the intestine from which they are known to arise. Both in architectural arrangement and in cytologic detail they almost regularly have features in common with the muscular layer and consequently they may readily be recognized as having arisen from this structure. In the case of the tumors presented in this paper the parenchyma was made up of specific tumor cells which approached very closely the mother tissue. The cells formed interlacing bands or whorls running in different directions. They were spindle shaped or polygonal in outline, varying in size and shape and containing a round or vesicular nucleus. The nuclei were hyperchromatic and

showed occasional mitoses. Scattered in the parenchyma were also found multinucleated giant cells. The stroma was very scant and consisted of a small amount of poorly vascularized loose connective tissue (Figs. 1 and 2).

Although the tumor mimics very closely smooth muscle tissue it may on occasions digress widely from the normal and assume a picture closely resembling spindle cell or fibrosarcoma. Some of the cases reported here were first diagnosed as fibrosarcoma, but after more thorough studies, a change in diagnosis to leiomyosarcoma was made. Although cases of fibrosarcoma of the intestine have been reported in the literature we are nevertheless inclined to believe that they are very rare.

Lymphosarcoma. Generally speaking these tumors are fairly rapidly growing with a tendency to grow expansively and metastasize early. Their rapid growth is associated with degeneration, necrosis, hemorrhage and perforation. There were 4 cases of lymphosarcoma in this series, 3 arising in the small in

Fig. 3. Photomicrograph of lymphosarcoma. Hematoxylin and eosin stain, $\times 80$.

Fig. 4. Photomicrograph of reticulum cell sarcoma. Hematoxylin and eosin stain, $\times 80$.

testine and 1 in the appendix. The growth was either lobulated or nodular, often soft and friable with tendency to ulcerate and hemorrhage. On section the tumor appeared homogeneous, grey pink or yellow in color. In 3 instances the tumor protruded into the lumen of the bowel and was the cause of acute intussusception. The bulk of the growth was usually confined to the mucosa or submucosa, although it may infiltrate the muscular and serous coats.

The close similarity in both architectural pattern and cell morphology of the tumor cells to the lymphoid structure of the intestine is striking and at once suggests a genetic relation. Microscopically the tumor parenchyma was made up of cells which bore a striking resemblance to the small lymphocyte commonly seen in the lymph follicles of the intestine. The cells were small and round, of about the same size and shape as a lymphocyte. The nucleus was also round, hyperchromatic and occupied the major portion of the cell substance, while the cytoplasm was scant and

formed but a narrow rim surrounding the periphery of the nucleus. Mitotic figures were frequently encountered and designated a high degree of malignancy. The structural arrangement of the cells varied somewhat in different tumors. In places the cells were found crowded together into dense nests with very little intercellular connective tissue stroma to support them; in others they assumed a more follicular arrangement. The mucosa overlying the tumor was usually intact and well preserved. There was a tendency, however, for the tumor to invade the muscular coat and occasionally also the serosa (Fig. 3).

Reticulum cell sarcoma. A review of the literature reveals a wide discussion of the genesis of reticulum cell sarcoma. Some investigators classify it as a form of lymphosarcoma, while others consider it to be a type of fibrous connective tissue growth. From the present study it appears to be more closely allied to the lymphosarcomatous group than the fibrous connective tissue forms of neoplasm. The parenchymal cells resemble more closely

Fig. 5. Photomicrograph of neurofibrosarcoma. Note palisading of cells and rosette formation. Hematoxylin and eosin stain, $\times 80$.

Fig. 6. Higher magnification of Figure 5. Hematoxylin and eosin stain, $\times 215$.

the lymphocyte described in the lymphosarcoma, while the stroma is somewhat more abundant and forms a fine fibrillar or reticular structure.

There were 3 cases of reticulum cell sarcoma, all arising from the small intestine. The structural pattern and cell morphology of the tumors were fairly uniform in all cases. Grossly the tumors were partly firm and partly soft and friable, arising as a rule in the submucosa and spreading out in all directions. On section the surface was a homogeneous gray or pink tissue. In one instance the lesion appeared as an ulcerated cauliflower growth with elevated edges. When this was cut across, a milky fluid escaped from the cut surface. In another case the tumor invaded the wall of the bowel and caused a tubular narrowing of the lumen for a distance of several inches.

Microscopically the tumor parenchyma consisted of polygonal cells varying considerably in size and shape and arranged in groups or nests. The nuclei were irregular in outline and stained deeply. Mitotic figures were fre-

quently encountered designating a high degree of malignancy. The stroma was moderate in amount and showed a fibrillar or reticular arrangement. The primary site of the tumor was in the submucosa from which it spread out in an irregular fashion toward the muscularis. The mucosa as a rule was uninvolved and left intact; in one case it was ulcerated. The lymphatic spaces within the wall of the affected bowel were dilated and filled with tumor tissue. The adjoining lymph nodes and fat were also infiltrated with the tumor (Fig. 4).

Neurofibrosarcoma. This type of tumor is very uncommon in the intestinal tract. It occurred in one instance in this series. Its origin can be traced to the tiny nerve fibers in the muscular coat. In the present series the tumor was located in the rectum and consisted of a nodular mass, partly firm and partly soft. On section it presented a granular yellow gray surface with multiple small hemorrhages.

Microscopically the tumor was made up of spindle shaped cells of various size. The ar-

arrangement of the cells was rather unique in character. In places they formed interlacing bands or pseudorosettes, while in others they assumed a palisade arrangement. Mitotic figures were rather few in number indicating a low grade malignancy (Figs. 5 and 6)

ANALYSIS OF STUDY

The clinical picture presented by this group of cases of sarcoma of the intestine merits some detailed description though in many respects the tumors followed the pattern previously described by many authors. The diagnosis of these tumors is often beset with many difficulties. The early symptoms and signs are by themselves not distinctive and are similar to those associated with other forms of intestinal malignancy. In certain cases the difficulties in arriving at a diagnosis may appear insurmountable. The laboratory tests although of great value are found to be by no means infallible.

Practically all the patients presented past histories which may have had bearing on their illness. Analysis of the diagnostic facts relating to these tumors shows that pain is the most constant subjective symptom and is usually described as cramp like in character. It occurred in more than 70 per cent of the present series. Loss of weight was not a frequent complaint and most of the patients appeared well nourished when first examined. Constipation alternating at times with diarrhea was a more frequent complaint.

The disease often pursued a chronic course. The earliest treated patients dated the onset of their illness to 4 to 7 days prior to hospitalization the latest 2 years giving the average duration of symptoms of 6 months. When complications set in the onset of symptoms was acute and of short duration. Intestinal obstruction perforation and massive hemorrhage are described as the more common forms of complication of the disease.

Physical examination revealed certain significant findings. The majority of the patients showed a secondary anemia which was proportionate in degree to the loss of blood. An abdominal mass was felt in 60 per cent of the patients the mass was either fixed or freely movable and often tender to palpation.

Among the various forms of nonepithelial malignant tumors of the intestinal tract, the following are most commonly encountered: lymphosarcoma, leiomyosarcoma, reticulum cell sarcoma, fibrosarcoma, spindle cell sarcoma, endothelial sarcoma, and Hodgkin's disease. In the present series four varieties of sarcoma were found and described namely lymphosarcoma, leiomyosarcoma, reticulum cell sarcoma, and neurofibrosarcoma. Of these various forms, lymphosarcoma is most common although in the present series the leiomyosarcoma outnumbered the lymphosarcoma in the ratio of approximately 2 to 1.

Sarcoma of the intestinal tract is as a rule a primary lesion and for a long time confines its growth to the bowel. As the disease progresses, the growth extends to involve the entire thickness and circumference of the intestine and even projects into the lumen or forms a bulge on its exterior but its tendency is to localize in the bowel and not metastasize. In some instances however it tends to extend into adjoining structures, especially into regional lymph nodes. This is particularly true in the cases of the lymphosarcoma and reticulum cell sarcoma. When the mucosa is also involved in the tumor process, ulceration usually follows. These changes are responsible at times for a host of symptoms. Under such circumstances bleeding may take place from the ulcerated intestinal wall and blood may appear in the stools. Thus 8 of the patients in this series showed tarry stools which reacted positively to benzidine, and 2 showed gross hemorrhages. Metastasis in the case of the lymphosarcoma and reticulum cell sarcoma takes place by the usual route through the lymph channels. In the case of the other forms of sarcoma, the spread is usually through the venous route.

In view of the present study of these cases and in correlation of the data with the various theories offered on the histogenesis of sarcoma of the intestine, we are inclined to consider these tumors as neoplasms arising from specific constituents of the intestinal wall. Throughout the entire series of cases, the histologic picture presented by the tumors bore a striking morphologic resemblance to the tissue from which they arose. Thus, the leiomyosar-

coma closely resembled the smooth musculature of the intestine, and the lymphosarcoma resembled the lymphoid tissue normally present in the intestinal mucosa. The reticulum cell sarcoma bore a morphologic resemblance to the large, pale staining cells forming the reticulum of the lymph follicles and there is no doubt as to the origin of this tumor from that structure. It is held by some that this tumor is of fibroblastic origin and by others, that it is of lymphoid origin. From the present study of the morphology of this tumor we are more inclined to believe that it arises from lymphoid tissue. Its structural pattern site of origin way of growth and its spread through the lymph stream rather than the venous channels is most suggestive of lymphoid origin. The neurofibrosarcoma consists of a mixture of nerve fibers and connective tissue and there is no doubt therefore, as to the origin of this tumor from the nerve elements of the intestinal wall.

Diagnosis is invariably late, as it is dependent on the onset of symptoms and it is well recognized that unfortunately the early symptoms of the sarcoma of the intestine are vague and apt to be confused with those of other lesions in the intestine. There is of necessity a latent period between the earliest tumor formation and the patient's awareness of something amiss and the duration of this period cannot be established at present. Owing to the low grade of malignancy of some of these growths, by the time the disease has produced symptoms of hemorrhage obstruction or perforation it is nearing the terminal stage. In the present series an accurate diagnosis of sarcoma was not made in any of the patients preoperatively and in many instances a correct interpretation of the lesion was not made until a histologic examination of the specimen

was done. In reviewing the cases presented we note several clinical facts. First in some of the cases of acute involvement the process was ushered in by the classic syndrome of sudden hemorrhage or sudden intestinal obstruction. In most of the cases the findings were corroborated at operation. Second the largest group of cases existed in which there was no definite clinical evidence suggestive of the presence of a neoplasm. Roentgen studies of these neoplasms are often helpful in locating the site of origin of these tumors and rendering diagnosis more accurate.

Little need be said of the prognosis in cases of intestinal sarcoma. If the condition is discovered early long before metastasis has had a chance to occur and complete resection of the lesion is done a more favorable prognosis may be rendered. This holds particularly true in the more slowly growing tumors such as the leiomyosarcoma and neurofibrosarcoma which grow slowly and metastasize late in the disease. The ideal treatment is complete removal if possible. When the lesion is discovered late permitting metastasis to occur, the prognosis as in other malignant tumors is rather poor.

CONCLUSIONS

Fifteen cases of sarcoma of the small and large intestine are reviewed. In 7 of these the lesion was a leiomyosarcoma in 4, lymphosarcoma in 3, reticulum cell sarcoma, and in 1, neurofibrosarcoma.

The diagnosis of sarcoma of the intestinal tract is difficult as it simulates other lesions of the intestine.

THE TREATMENT OF SEVERE INTRACRANIAL INFECTION BY REPEATED INTRAVENTRICULAR INJECTION OF PENICILLIN

Theoretical and Practical Considerations

R D WYKE, M.B. B.S. Sydney Australia

UNDER the impetus provided by the recent war penicillin has eclipsed the sulfonamides in the results achieved in the treatment of intracranial infections and has provided the physician with a powerful addition to his clinical armamentarium. Combination of both penicillin and sulfonamides has achieved even greater miracles in central nervous system infections. Nevertheless, although the mortality of intracranial infection has thus been greatly reduced in the face of a purely medical attack, there yet remains a group of cases in which the mortality and morbidity is high.

It is in these cases that a combined attack by both physician and surgeon utilizing all the general and special therapeutic methods at their command in an endeavor to bring the antibacterial agents into the closest possible relationship with the infecting organisms for as long as possible can materially improve the outlook. Especially is this so in cases of purulent meningitis and ventriculitis, cerebral abscess, posttraumatic intracranial infections and those intracranial lesions secondary to ear, nose, and throat infections.

A series of these cases, the first of which has been reported elsewhere (Wyke and Vanderfield 1946) is being studied by the writer. The present paper deals with the theoretical and practical considerations upon which the intraventricular method of treatment is based together with certain general suggestions regarding the management of severe intracranial infections. Detailed discussion of other cases in the series, and results of special investigations relating to certain problems arising from the present paper will be reported later.

Up to the present, no systematic account of the theory and practice of the intraventricular method of administering penicillin has appeared in the literature, although the procedure has been employed sporadically in various centers on numerous occasions.

Before turning to a consideration of the practical technical procedures involved in the method of treatment certain theoretical considerations upon which its clinical application depends, will be discussed in detail.

FACTORS GOVERNING THE PASSAGE OF PENICILLIN FROM THE BLOOD STREAM INTO THE CEREBROSPINAL FLUID CIRCULATION

It is apparent that penicillin can traverse the blood brain barrier slowly in two directions under normal conditions, passing either from the blood stream into the cerebrospinal fluid or vice versa. The evidence for this will be discussed. However the quantitative aspects of this phenomenon constitute the significant feature, supplying the answer to the problem as to whether an adequate bacteriostatic concentration of the drug can be built up and maintained in the cerebrospinal fluid from doses administered systemically. The

temporal relations of the $\frac{\text{serum}}{\text{C.S.F.}}$ penicillin ratio will form the subject of a later communication but sufficient work has been done to date to suggest certain conclusions.

Early in the therapeutic history of the drug, it was claimed (Abraham and associates, 1941) that intravenous injection of penicillin into cats did not lead to the excretion of significant amounts of the drug into the cerebrospinal fluid. Later Rammelkamp and Keefer (1943) were unable to demonstrate any penicillin in the cerebrospinal fluid of man following single

intravenous doses of 10 000 to 20,000 Oxford units. The same result was reported in a case receiving penicillin by the continuous intravenous drip method at the rate of ~ 500 to 3,000 units per hour even after 24 hours of such therapy. In addition Fleming (1943) comparing blood and cerebrospinal fluid concentrations of penicillin during intramuscular administration concluded that excretion of the drug into the cerebrospinal fluid was negligible. Similar observations were reported by Keefe and associates (1943) Struble and Bellows (1944) and Dolphin (1944).

Officer Loewenthal and Perry (1944) stated that their experience was the same, with both intramuscular and intravenous injections of the drug. They cited one case in particular in which no penicillin was detectable in the cerebrospinal fluid although the patient received 200 000 units of penicillin intravenously. Herrell, Nichols and Heilman (1944) were also unable to demonstrate penicillin in the cerebrospinal fluid of 4 patients with meningitis receiving 100 000 units per day by continuous intravenous infusion.

Notwithstanding these reports to the contrary, Rosenberg and Sylvester (1944) claimed that penicillin was excreted into the cerebrospinal fluid in bacteriostatically adequate amounts. They reported 8 cases of meningitis in which patients were treated with intramuscular or intravenous penicillin in doses of 20 000 to 40 000 Oxford units every 3 hours whose cerebrospinal fluid contained the drug in concentrations of 0.03 to 0.35 unit per cubic centimeter within 60 to 140 minutes.

However these authors noted as have others (e.g. Rammekamp and Keefe 1943, Smith, Duthie and Cairns 1946) that both absorption and excretion of the drug from and into the cerebrospinal fluid are very variable processes in different individuals especially in the presence of meningitic inflammation. The difference in the absorption rate in patients with normal and inflamed meninges is well seen in Figure 1 based on results obtained in the writer's series of cases in which it is apparent that absorption from the subarachnoid space is about twice as rapid in cases with meningitis as in those without. Similar results have been obtained by Cairns and his colleagues.

That the processes of excretion from the blood into the cerebrospinal fluid are also accelerated in meningeal infections is apparent from the work of Walker and Johnson (1945). These workers demonstrated that whereas under normal conditions in the meninges little penicillin enters the cerebrospinal fluid from the blood when the meninges are irritated by bacterial chemical or physical agents excretion is much increased. In normal monkeys with blood penicillin levels of 23.5 to 32.5 units per cubic centimeter no penicillin could be detected in the cerebrospinal fluid. But after inducing a meningeal reaction by coagulase of the animal or by intrathecal injection of air or bacteria 0.17 to 0.78 units per cubic centimeter were demonstrated in the spinal fluid. They noted that in man systemic (intramuscular) injection of penicillin 6 to 8 hours after performance of pneumoencephalography resulted in detectable amounts of penicillin being present in the cerebrospinal fluid within an hour.

Further weight is led to Walker and Johnson's hypothesis by recent work of Lange, Schwimmer and Boyd (1946). These authors demonstrated a three to fourfold increase in permeability of the capillaries in the meninges and choroid plexuses of patients with meningitis. They gave each of their cases an intravenous injection of 5 cubic centimeters of a 5 per cent solution of fluorescein and estimated the fluorescein content of the cerebrospinal fluid and blood 1 hour later. Using this method it was found that in normal people the fluorescein content of the cerebrospinal fluid does not exceed 300 γ per 1000 cubic centimeters whereas in the presence of meningitis there is an increase of up to 1000 γ per 1000 cubic centimeters. They also noted that waning of the meningeal inflammation was accompanied by a diminution in the fluorescein excretion and a rise in the $\frac{\text{plasma}}{\text{CSF}}$ fluorescein ratio.

Similar conclusions regarding the increased permeability of inflamed meninges are reported by Kinsman and d'Alonzo (1946). These results lend weight to the claim of Rosenberg and Sylvester that penicillin may be excreted into the cerebrospinal fluid in cases of meningitis but for clinical purposes it

As soon as the influence of the drug is removed multiplication may recommence, if the organisms have not been destroyed by the intrinsic antibacterial agents of the body (leucocytes and antibodies) or by penicillin present locally in bactericidal concentration. Penicillin must be kept continually in contact with all infected tissues (e.g. meninges and choroid plexuses) in adequate concentration until the natural body defenses have had time to deal with the infection (Florey and Jennings, 1945) and this cannot be achieved unless the drug is introduced directly into the cerebrospinal fluid.

For such reasons it is essential that adequate concentrations of penicillin should be maintained locally (i.e. in the cerebrospinal fluid especially within the ventricles) for sufficient time, in order to achieve complete destruction of the infecting organisms. This is particularly important in view of the fact that some organisms may become penicillin resistant although remaining pathogenic, when exposed to sublethal doses of the drug (Abraham and associates 1941; Rammelkamp and Maxon 1942; McKee and Houck 1943; Officer, Loewenthal, and Perry 1944; North and Christie, 1946). It is therefore important to determine the critical lethal concentration of penicillin for each of the organisms infecting the central nervous system. The relevant figures in this regard are given by Rammelkamp and Keefler (1943) and Walker and Johnson (1945).

It should be pointed out however that their results represent minimal concentrations determined *in vitro*. Other modifying factors are present under clinical conditions which tend to make the effective penicillin levels a little higher. These factors are considered elsewhere in the present paper.

It cannot be denied that clinical cure of meningitis has sometimes resulted in patients receiving penicillin by the systemic route alone (e.g. Price and Hodges 1944; Dawson and Hobby 1944; Tee, 1945; Milroy and Hughes 1945). However such cases provide no index of the efficacy of penicillin excretion into the cerebrospinal fluid as other factors are involved. Most of these patients receive or have received sulfonamide drugs as well as

penicillin at some stage of their treatment and these drugs (especially sulfadiazine) are capable of sterilizing the cerebrospinal fluid in infections with susceptible organisms. In addition many cases of intracranial infection especially those of meningococcal or pneumococcal origin have a concomitant bacteremia of intermittent type. Possibly the action of penicillin upon the systemic component of the infection may be partly responsible for the clinical improvement.

During the last 12 months further studies have appeared dealing with the passage of penicillin from the blood stream into the subarachnoid space and these support the earlier findings.

McDermott and Nelson (1945) have examined the problem with reference to the treatment of neurosyphilis with penicillin. In 70 patients they were unable to demonstrate significant amounts of penicillin in the cerebrospinal fluid by 4 different methods of assay, following parenteral dosage of penicillin in varying amounts. The results were unaffected by the presence or absence of neurosyphilis in the patients. Following intramuscular injections of 300 000 to 500 000 units of penicillin only 0.02 unit per cubic centimeter were demonstrable in the cerebrospinal fluid three to four hours later.

Following the work of Walker and Johnson (1945) cited earlier, Dumoff-Stanley and her colleagues (1946) examined the penicillin excretion into the cerebrospinal fluid in 14 patients, 6 of whom had intracranial infections. During intramuscular or intravenous injection of the drug penicillin was detected in the cerebrospinal fluid of 6 patients, 4 of whom had meningitis. The authors found that in 2 babies penicillin was detectable in the ventricular fluid while absent in that in the subarachnoid space. In another case the drug was present only in the last few cubic centimeters of 120 cubic centimeters of fluid withdrawn during pneumoencephalography. They conclude from these facts that the passage of penicillin from the blood stream into the cerebrospinal fluid occurs primarily through the choroid plexuses, as previously suggested by Cooke and Goldring (1945). They also found a serum concentration of at least 0.625 unit per

cubic centimeter to be the minimal blood level for adequate transchoroidal excretion of penicillin and that no patient with penicillin in his blood stream for less than 12 hours attained therapeutically effective concentrations of the drug in the cerebrospinal fluid. They therefore conclude that systemic administration of penicillin in the usual doses will not consistently yield measurable concentrations of penicillin in the cerebrospinal fluid.

More recently Schwemlein and associates (1946) reported that they were unable to detect significant concentrations of penicillin in the cerebrospinal fluid of patients with syphilis following intramuscular doses of 20,000, 40,000 and 200,000 units. However following massive intravenous administration by the continuous drip method effective levels were attained in cases of early syphilis. Their series consisted of 167 patients with primary or secondary syphilis, each of whom received 10 to 25 million units of penicillin given by continuous drip for 24 hours. Their results reveal that continuous intravenous administration of 10 to 20 million units produces bacteriostatically adequate concentrations in the cerebrospinal fluid. Use of such large doses in this manner is attended by certain reactions which the authors list as thrombophlebitis, nausea vomiting and azotemia; there were no meningeal reactions. Similarly Kaplan and associates (1946) were unable to detect any significant excretion of penicillin into the cerebrospinal fluid following intramuscular administration in neurosyphilis.

A study of the reports which have been discussed leaves the impression that the efficacy with which penicillin traverses the blood brain barrier under normal and abnormal conditions remains to be determined. It appears that the Atlantic Ocean separates two schools of thought in this matter. On the one hand is the English school headed by Florey and Cairns and including the original workers with the drug which denies the therapeutic efficiency of systemically administered penicillin in cases of severe intracranial infection and recommends direct introduction of the drug into the cerebrospinal fluid. On the other is the American school many members of which question the rationale of this method of

therapy (see Reese, 1945) and plead for parenteral administration only. However dissentient voices are heard in both groups.

In view of the unsettled state of the problem it is apparent that definitive studies dealing with the time relations between serum and cerebrospinal fluid levels of penicillin under normal and abnormal intracranial conditions should be undertaken. Such investigations are at present being pursued in Sydney and the results will be reported in a subsequent communication. However in spite of a few reports to the contrary it would appear justifiable, on the present available evidence, to conclude that therapeutically adequate concentrations of penicillin cannot be maintained within the cranial cavity by intermittent or continuous systemic administration of the drug in reasonable doses.

For this reason the writer believes that in all cases of intracranial infection with susceptible organisms except perhaps those of comparatively benign type penicillin should be introduced directly into the cerebrospinal fluid or circulation at repeated intervals, in addition to other therapeutic measures that may be undertaken. In severe cases the indications of which are outlined later such administration is preferable into the lateral ventricles of the brain with or without intraspinal administration as well.

DEVELOPMENT OF THE PROCEDURE OF DIRECT INTRODUCTION OF PENICILLIN INTO THE CEROBROSPINAL FLUID

Penicillin was first introduced directly into the cerebrospinal fluid of human patients in 1942 by Fleming (1943). His patient was a moribund case of streptococcal meningitis and the lumbar route was employed. Florey and Florey (1943) next reported a case of meningitis in which patient was treated with penicillin administered by the cisternal route and in the same year Smith, Duthie and Cairns (1943) and Barker (1943) described cases of pneumococcal meningitis successfully treated by intrathecal injections of penicillin. A further 23 cases of pneumococcal meningitis, some of whom received intrathecal injections of penicillin were reported by Rammelsberg and Keefer (1943). Other cases of meningitis

in which patients were treated in this manner were recorded by Keefe and associates (1943). Following these accounts Dolphin (1944) reported 3 cases of suppurative meningitis treated with intraspinal and intraventricular penicillin. This together with an account by McCune and Evans (1944) constitutes the first reference to use of the intraventricular route for the administration of penicillin in intracranial infection.

Reports of a further 16 cases of meningitis receiving daily intrathecal or intraventricular injections of penicillin were presented by Cairns, Duthie, Lewis and Smith (1944). Their cases were all patients suffering from pneumococcal meningitis; there were 4 deaths in the series. The penicillin was injected into both spine and ventricles in amounts of 4 to 10 cubic centimeters of a solution diluted in isotonic saline so that the concentration was 250 to 500 Oxford units per cubic centimeter. The average single dose into ventricles or spine was 3000 to 4000 units. Following injection of such a dose into the lateral ventricles penicillin was soon demonstrable in the lumbar fluid at a concentration of 0.4 unit per cubic centimeter (ten times that necessary to inhibit the growth of a sensitive pneumococcus) being present after 24 hours.

The fall in concentration and the relation between ventricular and spinal fluid levels of penicillin at successive intervals are seen in Figure 2 based on figures from the writer's series of cases. It is apparent that the intraventricular concentration falls off in an exponential manner; half concentration being attained in about 5 hours. Complete disappearance of the penicillin in the ventricles results in about 24 hours. The level of penicillin in the lumbar fluid does not parallel that in the ventricles but pursues a more rectangular course. It must be pointed out, however, that these values are merely averages, the limits of variation in different patients being relatively wide. However they agree closely with the results of Cairns and his colleagues.

Results similar to those described were noted by Officer Loewenthal and Perry (1944). The lumbar fluid of one of their cases contained 0.4 unit per cubic centimeter 14 hours after injection of 10 000 Oxford units of

penicillin into the right lateral ventricle. Penicillin introduced into the lateral ventricles soon spreads, in the absence of a cerebrospinal fluid block to all parts of the subarachnoid space (Cairns and associates 1944, Cairns 1945), and thence slowly into the blood stream (Rammellkamp and Keefe 1943) whence it is excreted into the urine and bile (Rammellkamp and Bradley 1943) and perhaps, in minute amounts back into the cerebrospinal fluid (see Fig 1).

Further cases of intracranial infection treated with penicillin administered into the spinal theca or cisterna magna were reported by Pilcher and Meacham (1943, 1944), Miller and Ross (1944), Officer Loewenthal, and Perry (1944), Waring and Smith (1944), Meads and associates (1944), Rosenberg and Arling (1944), Turner (1944), Evans (1944), Vickery and Dey (1944), Herrell, Nichols and Hellman (1944), Worth (1945), Baird (1945), Appelbaum and Nelson (1945), Sweet and associates (1945), Hall and associates (1946), and Naffziger and associates (1946). All of these workers recorded clinical results far better than any achieved previously and expressed belief in the efficacy of the direct method of treatment.

Later, Johnson and Walker (1945) successfully treated a patient with postoperative meningitis and ventriculitis due to the Staphylococcus albus by direct injections of penicillin into the ventricles through a rubber catheter fixed *in situ*. Baird (1945) used the ventricular route with success in a case of pneumococcal meningitis. Direct injection of penicillin into the ventricles in cases of meningitis was also recommended by Florey and Jennings (1945). In the same year further cases were described in which the intraventricular route was employed for the administration of penicillin. Cases of primary meningitis, as well as intracranial infections secondary to war wounds of the skull and brain which received this method of treatment were noted by Rewell (1945), Haynes (1945), and Rowe and Turner (1945). During the present year additional reports of the use of the ventricular route in the treatment of infected brain wounds, especially transventricular lesions, have appeared as the result of experiences in the recent war. Further

The upper graph represents the exponential decrease in concentration in the spinal fluid. The middle graph indicates the concurrent changes in serum concentration, while the lower one indicates the gradual excretion into the urine as the cerebrospinal fluid and serum concentrations fall.

cases of primary meningitis treated in this manner have also been recorded. Examples of these cases and the excellent results obtained are noted in papers by Hudson and associates (1946) Webster, Schneider and Lofstrom (1946) Smith, Duthie, and Cairns (1946) Turner (1946) Liras (1946) Jepson and Whitty (1946) Miller and Delohery (1946) and Wyke and Vanderfield (1946).

COMPLICATIONS OF DIRECT INTRODUCTION OF PENICILLIN INTO THE CEREBROSPINAL FLUID CIRCULATION

Ever since the introduction of penicillin as an addition to the clinical armamentarium in the attack on intracranial infection debate has arisen as to possible toxic effects of the drug upon nervous tissue when in direct contact

with it. For obvious reasons, consideration of this question is important in relation to any attempt at direct introduction of penicillin into the cerebrospinal fluid, especially into that within the cerebral ventricles. The evidence bearing on this problem will therefore be reviewed in detail.

The earlier workers with crude penicillin made no mention of reactions to intrathecal or intracisternal injection of the drug, but cases so treated were sporadic and the doses employed were relatively small. Early in the penicillin era it was suggested that the calcium salt of the drug was more toxic to the tissues than was the sodium salt (Florey and Jennings, 1942) but subsequent experience has not substantiated this (Herrell and Nichols, 1943; Gyöbri and Elmes, 1944; Florey and Jennings,

WYKE INTRAVENTRICULAR INJECTION OF PENICILLIN

1945) The elimination of impurities present in the earlier preparations may be partly responsible for this *volte face* (Berger, 1945 Committee on Medical Research 1946) What ever be the reason, it should be pointed out that in all the cases studied in Sydney by the writer the patients received intrathecal or intraventricular or both injections of the calcium salt of penicillin as prepared by the Commonwealth of Australia Serum Laboratories, and no toxic reactions were manifest.

In 1941 it was shown (Abraham and associates 1941) that intracisternal injection of penicillin in the rabbit produced no histological or functional disturbances. Following this report Florey and Florey (1943) Fleming (1943) Smith Duthie, and Cairns (1943) and Cairns and associates (1944) employed intrathecal or intracisternal injections of up to 4000 Oxford units in man without ill effects. Officer Loewenthal and Perry (1944) demonstrated the absence of toxic reactions to penicillin in the delicate tissues of the chick embryo and administered the drug intrathecally to human patients in repeated doses of 15 000 units, without complications.

As larger doses were employed dissentient reports appeared in the literature, especially in the United States Pilcher and Meacham (1943) and Rammelkamp and Keefer (1944) claimed that intrathecal injection of penicillin produced irritative changes in the meninges. In a brochure published by Merck and Co (1943) headache vomiting pleocytosis and increase in pressure in the cerebrospinal fluid were noted as following intrathecal injection of 10 000 Oxford units of penicillin.

In England Cairns and associates (1944) described systemic reactions following intraventricular injection of 3000 to 4000 units of penicillin. These manifestations consisted of a patchy erythema, sweating, pilomotor activity and vomiting lasting some 10 to 20 minutes after injection. However they pointed out that the preparation used was impure containing at most only 50 per cent of pure penicillin. Subsequently Johnson and Walker (1945) described a case of a 22 month old baby in which intraventricular injection of 50 000 units of penicillin diluted in 5 cubic centimeters of normal saline was followed by

unconsciousness in 1 hour and in 3 hours, by generalized convulsions. These authors believed the effect to be the result of an individual idiosyncrasy to the drug, and mentioned that they had injected up to 100,000 units of penicillin into the ventricles on other occasions without mishap. Idiosyncratic reactions to penicillin given by other routes have been noted (Pyle and Rattner, 1944 Vickers 1946) although they are rare.

Johnson and Walker's explanation may well be correct for the writer has repeatedly injected 50 000 units of undiluted penicillin solution (containing 10,000 units per c.c.) into the lateral ventricles of numbers of patients, including two babies under the age of 1 year, without the production of fits or other reactions. Miller and Delohery (1946) also make no mention of toxic reactions following intraventricular injection of 100,000 units of penicillin at repeated intervals. However Smith, Duthie, and Cairns (1946) mention 4 cases in which signs of lumbar meningeal and cord damage appeared following intrathecal injection of 100 000 units and Walker and Johnson (1945) had previously noted another. Siegal (1945) made a similar claim in the case of a patient receiving daily intrathecal injections of 40 000 units of penicillin but in this instance the sequelae were probably more the result of the disease than of the intraspinal therapy. In monkeys, Walker and Johnson (1945) described perianal paresthesia following intrathecal injection of 20 000 units of penicillin diluted in 1 cubic centimeter of normal saline. The effects were apparent in 10 minutes and lasted up to 1 hour. These authors suggested that lumbar radiculitis and arachnoiditis were possible complications of massive intraspinal therapy with penicillin. They also noted the occurrence of a transient increase in cell count in the spinal fluid following intrathecal injection of penicillin. The same phenomenon (i.e. pleocytosis) has been encountered twice by the writer following intraventricular injection of the drug. This reactive pleocytosis appears to be far less common now than in the earlier days of the penicillin era, perhaps because of increased purity of the available preparations. Moreover, it appears that this reaction may not be due primarily to the penicillin (43)

WYKE INTRAVENTRICULAR INJECTION OF PENICILLIN

sufficient concentration (Buggs and associates 1946 Forgas and associates, 1946 Johnson and associates 1946 Walker and associates 1946) In the case of the latter 3 these disturbances are of such an order as to preclude their local application to the central nervous system Among the antibiotics at present available penicillin and streptomycin appear to have the least active convulsive components in relation to their antibacterial activity With these two agents there is a wide difference between the convulsive threshold and the effective therapeutic level (Johnson et al 1946)

Pathological evidence of irritant effects of penicillin on brain tissue has been obtained by Russell and Beck (1945) These workers found that functional and histological changes (hemorrhage and necrosis) occurred in the brains of rabbits in which concentrated penicillin solution (10 000 units per c.c.) was applied directly to the cerebral cortex Similar changes are also described in the brains of monkeys by Johnson and colleagues (1946)

The result of these investigations especially in the United States, has been to stimulate suspicion of the procedure of direct introduction of penicillin into the cerebrospinal fluid of human patients The culmination of these fears is expressed in an editorial in the recent *Year Book of Neurology* in which Hans Reese (1945) seriously questions the rationale of such methods of treatment and advises against their use

However the conclusion to be drawn from all these reports is not that they contraindicate intraspinal or intraventricular administration of penicillin but that there is a limiting amount of the drug varying with different animal species which may safely be brought into direct relationship with the central nervous tissue This appears to be about 10,000 Oxford units per cubic centimeter in man when applied directly to the motor cortex Provided a local concentration of this degree is not exceeded in the intraventricular fluid the direct introduction of penicillin into the lateral ventricles of the brain is an entirely safe proceeding

As has been previously pointed out the writer has repeatedly injected 50 000 units of penicillin into the lateral ventricles of pa-

tients varying in age from 2 months to 53 years, without untoward effects This dose is administered as 5 cubic centimeters of a solution of the calcium salt of penicillin in a concentration of 10 000 units per cubic centimeter

That such doses are well within the limits of safety in the case of human patients is well borne out by the experiences of many neurosurgeons in the recent war Accounts based on observations of hundreds of cases of post-traumatic intracranial infection from many theaters of war in which penicillin was introduced into the ventricles, subdural space or into brain cavities or applied directly to the cerebral cortex testify to the efficacy and safety of intraventricular injection of penicillin Reports by Florey and Cairns (1944), Cairns (1945), Worth (1945), Haynes (1945), Rowe and Turner (1945), Webster Schneider, and Lofstrom (1946), Turner (1946) Martin and Campbell (1946), Weaver and Frisham (1946), Smith Duthie and Cairns (1946) and Jepson and Whitty (1946) provide ample evidence of the value of the intraventricular method of treatment in cases both of primary and of secondary intracranial infections

CLINICAL INDICATIONS FOR REPEATED INTRODUCTION OF PENICILLIN INTO THE LATERAL VENTRICLES OF THE BRAIN

Officer, Loewenthal and Perry (1944) proposed the following principles to be observed in treating any disease with penicillin (1) the infecting organism must be sensitive to the action of penicillin (2) the active principle must be brought into contact with the organism in sufficient concentration (3) abscesses must be drained, (4) dead tissue must be removed These postulates are valid for intracranial infections, as well as for infections elsewhere With them in mind and in the light of the previous theoretical discussion the following criteria are suggested as guides to the selection of cases suitable for treatment by repeated intraventricular injections of penicillin Presupposed of course, is the availability of personnel and facilities for carrying out the necessary procedures

1 Any case of intracranial infection with a penicillin sensitive organism in which the

Fig. 2. The relative concentrations of penicillin in the ventricular and spinal cerebrospinal fluid following intraventricular injection of 0.000 units. The ventricular concentration falls off in an exponential manner while that in the lumbar fluid pursues a more rectangular course. A ventricular fluid, B lumbar fluid.

cerebrospinal fluid obtained at the initial lumbar puncture is obviously purulent with a cell count of over 600 polymorphonuclear leucocytes per cubic millimeter and at a pressure greater than 250 millimeters of water.

In all cases, an essential preliminary to the institution of the intraventricular method of treatment is bacteriological identification of the infecting organism. Whenever possible, this should be supplemented by quantitative estimation of its penicillin sensitivity. Even if identification of the organism and determination of its sensitivity has already been performed as a corollary to other methods of therapy the assay should be repeated either at lumbar or ventricular puncture, at the outset of intraventricular penicillin therapy and in some cases, during treatment by this method.

This is especially important in cases in which the intraventricular method of treatment is initiated by failure to respond to medical therapy with sulfonamides or penicillin as the infecting organism may belong to a penicillin insensitive group or have developed resistance to the drug during treatment. In addition, some

strains of organisms usually considered unresponsive to penicillin may be sensitive to its action. An example of this is Pittman's (1931, 1933) S (b) strain of *Hemophilus influenzae*, which has recently been shown to be sensitive to the action of penicillin (27) to about the same degree as a standard staphylococcus. Forgas and his colleagues have successfully treated with penicillin a patient with influenza meningitis due to this organism.

2 Cases of intracranial infection with an organism of high virulence or with organisms which are only sensitive to relatively high concentrations of penicillin.

The previous discussion has shown that high concentrations of penicillin cannot be attained or maintained in the cerebrospinal fluid within the cranium by systemic administration of the drug. Therefore, in order to maintain high local concentrations of penicillin in both ventricles and subarachnoid space, it should be introduced directly into the cerebrospinal fluid circulation by intraspinal and intraventricular injection. This is especially important in babies and young children and may be performed with ease by fontanel puncture if the bregma has not completely closed. Any case of pneumococcal meningitis in infants is a special indication for the early use of the intraventricular route and it should be employed more often in such cases in view of the relative frequency and high mortality of this disease for in 642 cases of meningitis in children, Lindsay Rice and Selinger (1940) found 11.4 per cent to be due to pneumococcus. Institution of repeated intraventricular injections of penicillin may be a life-saving measure in these cases. An example of this is provided by two babies suffering from pneumococcal meningitis recently seen by the writer who were considered to be moribund, and in whom systemic and intraspinal therapy had failed to produce any response. Following 6 daily intraventricular injections each of 30,000 units of penicillin, both patients recovered completely.

3 Cases of intracranial infection with a susceptible organism which fail to show early and progressive improvement under medical treatment.

Any case of intracranial infection in which there is not a satisfactory response to systemic

administration of penicillin, or the sulfonamides or both with or without intraspinal penicillin therapy should receive intraventricular injections of the drug if the causative organism is penicillin sensitive. Especially does this apply to any comatose patient with intracranial infection who does not recover consciousness within 12 hours of instituting medical treatment or any case in which papilledema develops during medical treatment.

4 Cases of intracranial infection with a penicillin sensitive organism where a cerebrospinal fluid block is expected or suspected

Cerebrospinal fluid block may occur anywhere in the ventricular or subarachnoid space in cases of intracranial infection. The common sites are in the posterior cranial fossa in the sylvian aqueduct within the foramen of Monro in relation to the tentorium cerebelli or in the lumbar theca. It has been suggested that herniation of the cerebellar tonsils through the foramen magnum as a result of the high intracranial pressure is a common cause of block in cases of meningitis (Shalom 1945). However this has not been a common feature in the writer's cases. More frequent causes of block are the formation of fibrous adhesions which obstruct the free flow of cerebrospinal fluid or compression and displacement of the ventricular system by the development of an intracranial abscess. But in the presence of an intracranial abscess tonsillar or calcarine herniation may become a potent cause of block especially if frequent lumbar punctures are performed.

The frequency with which cerebrospinal fluid block occurs as a result of adhesion formation depends upon a number of factors the most important of which will be discussed further.

a The nature of the infecting organism The development of cerebrospinal fluid block and consequent hydrocephalus appears to be most frequent in pneumococcal infections of the nervous system. It is less frequent with *Staphylococcus aureus* infections, and still less in those due to meningococci and streptococci. The formation of basal adhesions is a complication of considerable significance in pneumococcal meningitis as it may lead to death of

the patient, even though the cerebrospinal fluid has been completely sterilized. For this reason the use of agents to prevent formation of the fibrous adhesions which later become organized into dense fibrous bands is under consideration. Heparin has been suggested as a possible solution to this problem (Signorelli and Friedman, 1945; Turner 1946) and the writer is at present investigating the possibility of introducing heparin or a fibrinolytic prepared from blood, into the ventricles along with the penicillin in an endeavor to prevent the formation of the primary adhesions which are the result of deposition of fibrin. Later these become organized (if the patient survives the infection) by fibroblastic permeation from the blood vessels and then constitute dense secondary adhesions which are intimately blended with the thickened arachnoid. If formation of the primary adhesions can be prevented the incidence of post-infective hydrocephalus, with its entailed mortality and morbidity will be reduced to a great extent.

These complications are becoming increasingly frequent as more and more patients survive intracranial infections which in other days were fatal. The use of sulfonamide drugs and penicillin inhibits bacterial activity but does not check the fibroblastic activity which proliferates in an attempt to organize the purulent exudate in the subarachnoid space. The result is the formation of adhesions and the conversion of the leptomeninges into a dense scar through which the cerebrospinal fluid cannot circulate. A series of such cases following sulfonamide therapy has been recorded by Bailey (1945) and the writer has seen several examples following treatment of meningitis with penicillin. Investigation of this problem demands urgent attention because it is of little use sterilizing the cerebrospinal fluid if the patient dies subsequently from the results of an obstructive hydrocephalus. Application of the principles detailed in this paper, and the institution of the intraventricular method of treatment at an early stage will often help to prevent adhesion and abscess formation nevertheless there will still remain a few cases in which adhesions form early in the disease. These cases perhaps, may be aided by pro-

phylactic utilization of some fibrinolytic agent along with the antibacterial drugs.

b Antifibrinolytic action of penicillin Certain organisms which infect the central nervous system possess fibrinolytic properties, which result from the activity of an enzyme complex (fibrinolysin, fibrinase) which they elaborate. Organisms differ in the activity of the fibrinase they produce, fibrinolysis being most active in the case of *Staphylococcus pyogenes* less so with *Streptococcus pyogenes*, and slight with pneumococci and meningococci. Different strains of the same organisms also display differences in fibrinolytic activity some strains being very active, while others (even in the case of *Streptococcus hemolyticus*) being almost inactive.

It has been shown by several workers (Rammelkamp 1942 Wilson 1943 Fleming 1943 1944) that the fibrinolytic activity of *Streptococcus hemolyticus* is inhibited by penicillin. This has been confirmed by Neter and Will (1944). More recently Dixon (1945) has demonstrated that fibrinolysis by *Staphylococcus pyogenes* is also inhibited by penicillin being completely stopped by *in vitro* concentrations of penicillin of 0.1 unit per cubic centimeter and greatly retarded by 0.05 unit per cubic centimeter. The phenomenon is independent of the presence of serum and may reasonably be expected to take place in the cerebrospinal fluid. This antifibrinolytic activity appears to be a property of the active principle of the drug for it is related to the penicillin sensitivity of the organism. With penicillin resistant strains, fibrinolysis is unimpeded by the presence of the drug (Dixon 1945).

Nevertheless, the aforementioned data suggest that the introduction of a fibrinolytic agent, which is not inhibited by penicillin into the cerebrospinal fluid may be an integral part of the treatment of severe intracranial infections.

Cerebrospinal fluid block occurs long before the development of an abnormal response to the Queckenstedt test. One of the earliest indications of the occurrence of a block in intracranial infection is gradually increasing difficulty in obtaining fluid at lumbar puncture, even though it is not obviously purulent (Shalom 1945 Smith Duthie, and Cairns, 1946). Increasing yellowness of the spinal fluid obtained at successive spinal punctures for intrathecal injection is also suggestive of block. Another useful index of a developing block in a patient being treated by intrathecal injection of penicillin is a retardation of the fall off in concentration of the drug in the lumbar fluid. If no block is present the drug is absorbed and diffuses away so that its local concentration falls off decrementally in an exponential manner half concentration being reached in about 4 to 5 hours. Performing serial assays on the lumbar fluid, if a block is suspected (Fig 3) will often reveal that the concentration curve has lost its exponential character and is tending to plateau formation. This suggests a developing block, and occurs long before there is any detectable change in the Queckenstedt response. The higher the plateau the more complete the degree of block.

The development of such a phenomenon is a strong indication for treatment by the ventric

secondary to brain abscess or suppurating extracranial foci

Cases of posttraumatic infection especially where ventricular penetration has occurred, also fall into this group

The formation of a cerebral or cerebellar abscess is an important complication of primary or secondary intracranial infection and must always be considered in cases in which the disease becomes prolonged or is slow to clear up under medical therapy

The diagnosis of intracranial abscess may present extreme difficulty and will not be considered in detail in the present paper except to stress the value of electroencephalography as a diagnostic aid. Not only may the presence of an abscess be revealed by the appearance of an abnormal rhythm (see Fig. 4) but its location may be indicated by employing the procedures of 'phase reversal' and triangulation. However it should be pointed out in passing that a negative electroencephalographic tracing is not exclusive of abscess formation and for this reason in all suspected cases ventriculography should be carried out as a confirmatory step and penicillin injected into the ventricles through the burr holes introduced during the procedure.

Two types of abscesses occur within the cranium the acute and the chronic (or encapsulated) forms. The recent work of Clovis Vincent (1946) Pennybacker (1945) and Furlow (1945) suggests that the correct treatment of a cerebral abscess is excision after encapsulation has occurred. Direct surgical attack is contraindicated during the preliminary acute phase of abscess formation but it is during this expectant period that penicillin can play an invaluable part especially if introduced directly into the ventricles as well as by other routes. However in the early stages of abscess formation cerebral edema is generally marked and the consequent brain swelling may reduce the performance of a ventricular tap. Nevertheless even if such be the case the introduction of burr holes will permit irrigation of the cerebral subarachnoid space with penicillin solution. As the abscess becomes walled off its contents may be aspirated through a burr hole and its cavity filled with

Fig. 3. The course of penicillin concentration in the spinal fluid in cases of meningitis with developing cerebrospinal fluid block, as determined at serial lumbar punctures. As the block develops the absorption curve loses its exponential character and becomes plateau-like. penicillin solution and finally, when encapsulated it may be removed by radical excision together with any brain tissue that is obviously infected (King 1924 Fincher 1946 Sachs 1946). Excision of the abscess should be immediately preceded by intrathecal and intraventricular injection of penicillin as a prophylactic preoperative measure (qv) in some cases marsupialization of the abscess may be carried out.
